30 Abstract:

31 The sky is a natural heat sink that has been extensively used for passive radiative cooling
32 of households. Past experimental works have focused on maximizing radiative cooling
33 power of roof coating in hot daytime using static, cooling-optimized material properties.
34 However, the resultant overcooling in cold night or winter times exacerbates the heating
35 cost, especially in climates where heating dominates energy consumption. In this work,
36 we approach the thermal regulation from an all-season perspective by developing a
37 mechanically flexible coating that adapts its thermal emittance to different ambient

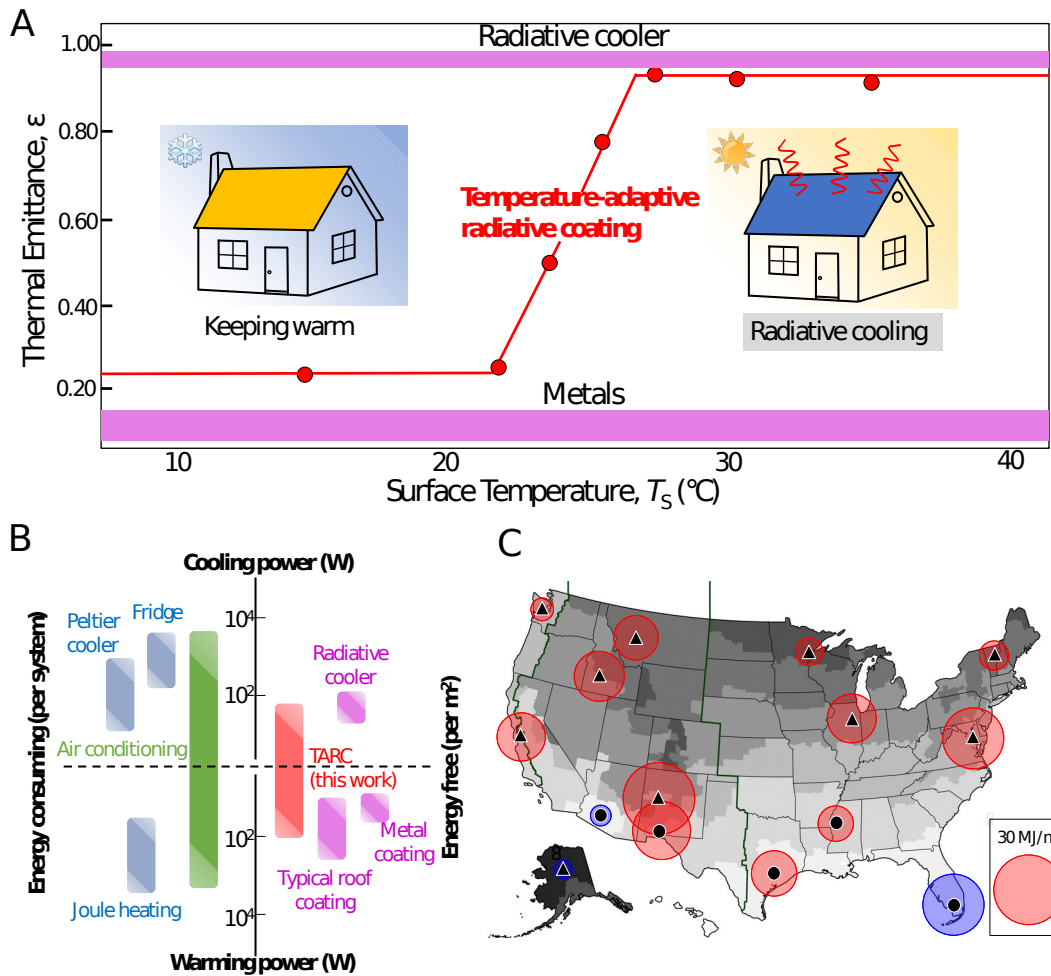

38 temperatures. The fabricated temperature-adaptive radiative coating (TARC)
39 automatically switches thermal emittance from 0.20 for ambient temperatures lower than
40 15 °C to 0.90 for temperatures above 30 °C, driven by a photonicly amplified metal-
41 insulator transition. The TARC is simulated to outperform all existing roof coatings for
42 energy saving in most climates, especially those with significant seasonal variations,
43 yielding a minimum cut in annual source energy consumption up to 3.65 GJ in the U.S.
44 for a typical single-family home.
45

46 **Introduction**

47 More than 40% of the total energy consumption in countries such as the United States is
48 in buildings, and within this portion of energy, about 48% is consumed on heating and
49 cooling to maintain a desirable indoor temperature (about 22 °C).¹ In contrast to most
50 temperature regulation systems that require external power input, the mid-infrared
51 atmospheric transparency window allows thermal radiation from the earth towards the
52 3 K temperature outer space, thus opening a passive avenue for radiative cooling of
53 buildings. This method to cool an outdoor surface, such as a roof, has been extensively
54 studied in the past,²⁻⁴ and is recently advanced by the development of daytime radiative
55 cooling⁵⁻¹⁰ using materials with low solar absorptance and high thermal emittance, in the
56 form of thin films,⁷ organic paints,⁸ or structural materials.⁹

57 Past research on daytime radiative cooling, despite their success in reducing cooling
58 energy consumption, typically used materials with fixed, cooling-optimized properties,
59 which efficiently emit thermal radiation even when the temperature of the surface is
60 lower than desired, such as during the night or in the winter. This unwanted thermal
61 radiative cooling will increase the energy consumption for heating, and may offset the
62 cooling energy saved in hot hours or seasons. This issue is well-acknowledged by the
63 research community and mitigation of the over-cooling becomes a timely demand.¹¹ To
64 cut the heating penalty from over-cooling, a few techniques were recently attempted for
65 switching off thermal radiative cooling at low temperatures (below 22 °C). Although
66 effective in switching, these techniques typically require either additional energy input^{12,13}
67 or external activation,¹⁴ and in some cases is achieved by mechanically moving parts.^{15,16}
68 It is highly desirable to develop dynamic structures that automatically switch off the
69 radiative cooling at low temperatures. Existing efforts in self-switching radiative cooling,
70 however, are either purely theoretical,¹⁷⁻²⁰ or limited to materials characterization with
71 little relevance to practical household thermal regulation.²¹⁻²⁴

 88 **its benefits for household thermal regulation. A.** Basic property
 89 of TARC in thermal emittance modulation and schematics for
 90 temperature management when used as a household roof coating. The
 91 data points are experimental emittance of a TARC. **B.** TARC in
 92 comparison to other thermal regulation systems, highlighting the
 93 unique benefit of TARC of being simultaneously energy free and
 94 temperature adaptive. **C.** Simulated minimum annual space
 95 conditioning source energy saving (SCSES_{min}) of TARC compared to
 96 other existing roof coating materials for different cities representing
 97 the 15 climate zones in the U.S. Red and blue circles indicate positive
 98 and negative SCSES_{min} values, respectively. The values are scaled to
 99 the area of the circles. Details of the simulation can be found in the
 100 Supporting Information.

101

102

103 In this work, we tackle this problem by designing and fabricating a flexible coating
 104 structure for all-season household thermal regulation. This temperature-adaptive radiative
 105 coating (TARC) automatically switches its thermal emittance to 0.90 from 0.20 when the
 106 surface temperature rises above $\sim 22^\circ\text{C}$, delivering high radiative cooling power
 107 exclusively for the high temperature condition (Fig. 1A). The solar absorptance is also
 108 optimized at ~ 0.25 (solar reflectance 0.75) for all-season energy saving in major U.S.
 109 cities (Fig. S7), a value comparable to that of a commercial white roof coating. The
 110 TARC is the first energy-autonomous and temperature-adaptive thermal regulation
 111 system (Fig.1B) to demonstrate effective surface temperature modulation in an outdoor
 112 test environment. Extensive simulations were performed based on the device properties
 113 and the global climate database, which show advantages of TARC over all existing roof
 114 coating materials in energy saving for most U.S. cities in different climate zones and
 115 global cities (Fig. 1C and Fig. S8). The energy saving by TARC not only brings
 116 economic benefits but also contributes to environmental preservation by cutting off
 117 green-house gas emission.

122 **Figure 2. Basic properties of TARC and experimental**
 123 **characterization.** **A.** Schematics of the structure (i), materials
 124 composition, and working mechanism (ii - iii) of the TARC. T_{MIT} denotes
 125 the metal-insulator transition temperature. Subpanels (iv) and (v) show

126 the simulated distribution of electric field intensity below and above
127 the transition temperature, respectively, when electromagnetic waves
128 with a wavelength of 7.8 μm were normally incident on the TARC
129 structure. **B.** A photo (2 cm \times 2 cm) and an SEM image of a TARC,
130 showing high flexibility and structural consistency with the design. **C.**
131 Thermal infrared (TIR) images of a TARC compared to those of two
132 conventional materials (references) with constantly low or high thermal
133 emittance, showing the temperature-adaptive switching in thermal
134 emittance of TARC. **D.** Solar spectral absorptance and thermal spectral
135 emittance of TARC at a low temperature and a high temperature,
136 measured by a UV-vis-IR spectrometer with integrating sphere and a
137 Fourier transform infrared (FTIR) spectrometer, respectively (solid
138 curves), showing consistency with theoretical predictions (dashed
139 curves). The arrow at 7.8 μm denotes the wavelength where subpanels
140 (iv) and (v) of **A** are simulated.

141

142 **Basic properties of TARC**

143 The TARC is developed based on the well-known metal-insulator transition (MIT) of the
144 strongly correlated electron materials $\text{W}_x\text{V}_{1-x}\text{O}_2$,²⁵ and the transition temperature (T_{MIT}) is
145 tailored to about 22 $^\circ\text{C}$ by setting the composition x at 1.5%.²⁶ A lithographically
146 patterned two-dimensional array of thin $\text{W}_x\text{V}_{1-x}\text{O}_2$ blocks are embedded in a BaF_2
147 dielectric layer which sits on top of an Ag film (Fig. 2A). In the insulating (I) state of
148 $\text{W}_x\text{V}_{1-x}\text{O}_2$ at $T < T_{\text{MIT}}$, the material is largely transparent to the IR radiation in the 8-13 μm
149 spectral window, so the incident IR radiation is reflected by the Ag mirror with little
150 absorption.²⁷ In contrast, the $\text{W}_x\text{V}_{1-x}\text{O}_2$ becomes highly IR absorptive when it switches to
151 the metallic (M) state at $T > T_{\text{MIT}}$,²⁷ and the absorption is further amplified by the designed
152 photonic resonance with adjacent $\text{W}_x\text{V}_{1-x}\text{O}_2$ blocks as well as with the bottom Ag layer
153 via the $1/4$ -wavelength cavity. According to the Kirchhoff's law of radiation,²⁸ the thermal
154 emittance equals the thermal absorptance and switches from low to high values when the
155 temperature exceeds T_{MIT} . Consequently, strong radiative cooling is turned on in
156 operation exclusively at high temperatures, leaving the system in solar-heating or keep-
157 warm mode at low temperatures. The fabrication process and structural parameters can be
158 found in the Methods section and Fig. S1.

159 Figure 2B shows optical images of a fabricated TARC with high flexibility for versatile
160 surface adaption, as well as a microscale structure consistent with the design. The global
161 emittance switching was first examined by a thermal infrared camera (Fig. 2C). The
162 TARC surface was imaged together with two reference samples having similar thickness
163 but constantly low thermal emittance (0.10, copper plate) or high thermal emittance
164 (0.95, black carbon-fiber tape), respectively. While the thermal emission of the reference
165 samples appears not strongly temperature sensitive from 20 to 30 $^\circ\text{C}$, the TARC shows a
166 dramatic change, corresponding to the switch in thermal emittance at the MIT around 22
167 $^\circ\text{C}$.

168 Spectral properties of the TARC were measured by a UV-vis-IR spectrometer and
 169 Fourier-transform infrared spectroscopy (FTIR) for the solar and thermal-IR wavelength
 170 regimes, respectively, and are shown in Fig. 2D. The solar absorptance (A , 0.3-2.5 μm) is
 171 about 0.25, and the sky-window emittance (ϵ_s , 8-13 μm) is about 0.20 in the I state and
 172 0.90 in the M state, consistent with theoretical simulations and other characterization
 173 results (Fig. S2 and Fig. S3).

174

175 **Figure 3. Characterization of intrinsic radiative cooling power**
 176 **of TARC in a cold vacuum chamber. A.** Schematics of the
 177 experimental setup, showing a thin heater membrane covered by
 178 TARC or an Al foil and suspended in a cryogen cooled vacuum
 179 chamber. The Al foil reference is used to cancel out the effect of
 180 thermal loss via conduction. **B.** Measured areal cooling power of TARC
 181 as a function of temperature in vacuum. Fitting of the $P_{\text{cool}}(T)$ at I and M
 182 states by the Stefan-Boltzmann radiation law gives ϵ_s equal to 0.20 and
 183 0.90, respectively. -

184

185 Characterization of radiative cooling power

186 The emittance switching of TARC enables modulation of radiative cooling power in
 187 response to ambient temperature, which was first measured in vacuum shown in Fig. 3A.
 188 A heater membrane was suspended by thin strings in a vacuum chamber, which was
 189 cooled with dry ice to $-78\text{ }^\circ\text{C}$ to minimize radiation from the chamber walls. A piece of
 190 Al foil with $\epsilon_s \approx 0.03$ or an TARC with the same size was attached to the top of the heater
 191 in two separate measurements. At each stabilized sample temperature T , the heating
 192 powers needed for the two coating scenarios are denoted as $P_{\text{Al}}(T)$ and $P_{\text{TARC}}(T)$,
 193 respectively. The intrinsic cooling power contributed by the TARC was calculated as
 194 $P_{\text{cool}}(T) = P_{\text{TARC}}(T) - P_{\text{Al}}(T)$. The Al foil reference was used to calibrate background heat
 195 loss from thermal conduction. Figure 3B plots the calibrated cooling power, showing an
 196 abrupt increase in $P_{\text{cool}}(T)$ when T increases above the MIT temperature. $P_{\text{cool}}(T)$ at the I
 197 state and M state are well fitted by the Stefan-Boltzmann radiation law, with the thermal
 198 emittance extracted to be about 0.20 and 0.90, respectively, consistent with the spectrally
 199 characterized results (Fig. 2D). Note that effect of radiation from the chamber wall (about

200 -78 °C) was accounted for and corrected in the calibration. A constant factor of β (≈ 0.7)
 201 is introduced here to account for the difference between the vacuum and ambient
 202 measurement conditions (details in Fig. S4).

203

204

205 **Figure 4. Characterization of TARC in an outdoor environment**
 206 **and calculated thermal load advantage.** **A.** Surface temperature
 207 of TARC, a commercial dark roof coating ($A = 0.70$, $\epsilon_s = 0.90$), and a
 208 commercial white roof coating ($A = 0.15$, $\epsilon_s = 0.90$) in an open-space
 209 outdoor environment recorded over a day-night cycle. The
 210 measurement was taken at 2020-07-05, Berkeley (37.91 °N, 122.28
 211 °W). The solid and dashed curves are experimental data and
 212 simulation results based on local weather database, respectively.
 213 Measurements starting from 14:00 local daylight time (LDT) were
 214 performed with the direct solar radiation blocked. The data after
 215 sunset show a clear sign of TARC shutting off radiative cooling as
 216 temperature falls below T_{MIT} . **B.** Measured ambient cooling power of
 217 TARC and white roof coating with direct solar radiation blocked in the
 218 outdoor environment. **C.** Calculated surface temperature (T_s) and the
 219 corresponding emittance (ϵ_s) mapping of TARC over 24 hours and the
 220 full year for Berkeley, California, as well as the space conditioning
 221 source energy saving (SCSES) of TARC compared to all other materials
 222 with fixed solar absorptance (A_{ref}) and thermal emittance (ϵ_{ref}). The
 223 icons in the SCSES map correspond to those used in Fig. 1C, denoting

224 the optical parameters (A , ϵ_s) of the strongest rival to TARC in source
225 energy saving for the local climate.

226

227 **Demonstration of performance in outdoor environment**

228 The actual outdoor performance of the TARC is demonstrated in Fig. 4. The surface
229 temperatures (T_s) of the TARC, together with a dark roof coating product (BEHR #N520
230 Asphalt Gray) and a cool (white) roof coating product (GAF RoofShield White Acrylic),
231 were recorded over 24 hours on a sunny summer day on a rooftop in Berkeley,
232 California, with a careful design of the measurement system to minimize the effects of
233 artifacts (see Fig. S5).

234 From 00:00 to 09:00 local daylight time (LDT) when the ambient temperature was below
235 T_{MIT} , the TARC was 2 °C warmer than the two reference roof coatings, arising from the
236 low thermal emittance ($\epsilon_s = 0.20$) of the TARC in the I-state and thus a lower radiative
237 cooling power than the references ($\epsilon_s = 0.90$). The 2 °C temperature elevation is
238 consistent with adiabatic simulation results based on these nominal emittance values and
239 the local weather database (see Supporting Information). From 09:00 to 14:00 LDT when
240 the samples were in direct sunlight, T_s was dominated by the solar absorption in balance
241 with radiative cooling and air convection, and the differences between the samples agree
242 with the simulated results assuming the solar absorptance A to be 0.15, 0.25, and 0.70 for
243 the white roof coating, the TARC, and the dark roof coating, respectively. After 14:00
244 LDT, a shield was erected to intentionally block direct solar radiation to the surface of the
245 samples, which imitates the scenario of a cloud blocking the sun but with the rest of the
246 sky mostly clear. A convergence of the T_s curves was quickly observed for all three
247 samples, an indication that the thermal emittance of the TARC in the M state is close to
248 that of the two references (0.90). This condition persists for a few hours until T_s started to
249 drop below $T_{MIT} = 22$ °C. After this point, TARC grew warmer than the two references,
250 with a final temperature difference of about 2 °C similar to the 00:00 to 09:00 LDT
251 period; this indicates that the TARC switched to the low-emittance I state. The 24-hour
252 outdoor experiments demonstrate the emittance switching and resultant temperature
253 regulation by TARC.

254 To directly compare their ambient condition cooling power ($P_{cool,amb}$), the TARC and the
255 white roof coating were heated to the air temperature with the direct solar radiation
256 blocked. $P_{cool,amb}$ refers to the power needed to balance the net heat loss from the surface,
257 namely, the thermal radiative heat loss minus the absorbed diffusive solar irradiance
258 power. The obtained $P_{cool,amb}$ values at a low and a high air temperature are plotted in Fig.
259 4B. The TARC exhibits a clear switching of $P_{cool,amb}$ by a factor over five across the MIT.
260 This is in stark contrast to the nearly constant $P_{cool,amb}$ around 120 W/m² for the white roof
261 coating, which is consistent with values (90 - 130 W/m²) reported in literature for
262 radiative cooling roofs.^{4,7,8}

263 **Space-conditioning energy savings potential in U.S. cities**

264 We performed extensive numerical simulations to analyze the performance of TARC in
265 household energy saving for the U.S. and global cities from an all-season perspective.

266 Details of the simulations are in the Methods section and the Supporting Information.
267 Figure 4C shows the simulated results for Berkeley where the measurements in Fig. 4A
268 & B were carried out. An hour-month map of T_s was calculated using a local weather file,
269 laying the basis for estimation of energy saving. We assume heating and cooling setpoints
270 $T_{\text{set, heat}} = 22 \text{ }^\circ\text{C}$ and $T_{\text{set, cool}} = 24 \text{ }^\circ\text{C}$,²⁹ and approximate that the building will need heating
271 when $T_s < T_{\text{set, heat}}$ and require cooling when $T_s > T_{\text{set, cool}}$. In hour-of-year i , we define
272 heating degrees $D_{h,i} = (T_{\text{set, heat}} - T_{s,i})_+$ and cooling degrees $D_{c,i} = (T_{s,i} - T_{\text{set, cool}})_+$, where
273 $x_+ = x$ if $x > 0$ or 0 otherwise. The annual average heating degrees and cooling degrees are
274 denoted by D_h and D_c , respectively.

275 We used past simulations of cool-roof energy savings to predict potential space-
276 conditioning source energy savings (SCSES) attainable by using TARC in place of
277 roofing materials that have static values of solar absorptance and thermal emittance
278 (Details in the Method section). The figure of merit of TARC is represented by $\text{SCSES}_{\text{min}}$,
279 the minimum value of SCSES found over existing conventional roofing materials - *i.e.*,
280 roof surfaces with values of A_{ref} and ϵ_{ref} contained in either of the two boxes shown in Fig.
281 4C. $\text{SCSES}_{\text{min}}$ is mapped for cities representing the 15 U.S. climate zones in Fig. 1C, as
282 well as for major global cities in Fig. S8. It can be seen that TARC provides a clear,
283 positive annual space-conditioning source energy savings relative to all existing roof
284 coating materials in most major cities, except for climates that are constantly cold (such
285 as Fairbanks and Reykjavík) or hot (such as Miami and Singapore) all year round. The
286 figure of merit map highlights the advantage of TARC, especially in climate zones with
287 wide temperature variations, day to night or summer to winter. For example, we estimate
288 for a single-family home in Baltimore, MD built before 1980, $\text{SCSES}_{\text{min}}$ is $22.4 \text{ MJ/m}^2\cdot\text{y}$,
289 saving 2.64 GJ/y based on a roof area of 118 m^2 .

290 The results in both Fig. 1C and Fig. 4C are based on the dominant resident building
291 prototype in the United States,³⁰ which is a single-family home built prior to 1980.
292 Minimum annual source energy savings per unit roof area for single-family homes and
293 apartment buildings built before 1980, between 1980 and 1999, and recently are
294 presented in Table S4.

295 **Conclusions**

296 A mechanically flexible, energy-autonomous, and temperature-adaptive radiative coating
297 (TARC) is developed for intelligent regulation of household temperature. This system
298 works on the basis of a thermally driven metal insulator transition in cooperation with
299 photonic resonance, and features a self-switching in thermal emittance from 0.20 to 0.90
300 at a desired temperature of about $22 \text{ }^\circ\text{C}$. These unprecedented properties enable switching
301 of the system from radiative cooling mode at high temperatures to solar-heating or keep-
302 warm mode at low temperatures in an outdoor setting. For most cities in the U.S. and
303 around the world, the TARC is predicted to outperform conventional roof materials in
304 cutting energy consumption for households. Combined with the possibility of mass
305 production (Fig. S9), this technology will bring broad benefit of building energy saving
306 and environment preservation.

393

394 **Materials and Methods**

395

396 **Preparation of the TARC**

397 675 μm-thick Si wafers were first covered with ~ 2 μm thick polyimide film (PI-2545,
398 HD MicroSystems LLC) via spin coating, which was then cured in a N₂-filled oven at
399 425 °C for 60 minutes. The polyimide film acts as an etching protection layer for the final
400 transfer process. W_xV_{1-x}O₂ thin films were grown on the polyimide layer using pulse laser
401 deposition (PLD). The PLD target was prepared by mixing WO₃ and V₂O₅ powders with
402 W:V atomic ratio at 1.5%, then made into 2.5 cm diameter round discs with a hydraulic
403 press. All W_xV_{1-x}O₂ thin films were deposited in 5 mTorr O₂ environment at 500 °C
404 substrate temperature, and the PLD laser energy was set at 321 mJ with 10 Hz pulse
405 frequency. 70 nm of W_xV_{1-x}O₂ was grown at a rate of 6 nm/min, followed by a post-

406 deposition anneal at 500 °C for 30 mins in the same 5 mTorr O₂ environment. The
 407 metamaterials patterns were made with standard photolithography, combined with
 408 etching of W_xV_{1-x}O₂ by SF₆ + O₂ in a plasma etching system. After removing the
 409 photoresist with acetone and O₂ plasma, 1.5 μm thick BaF₂ and 100 nm thick Ag layers
 410 were grown sequentially on top via thermal evaporation. The growth rates of BaF₂ and
 411 Ag were controlled at 20 Å/s and 2 Å/s, respectively.

412 In the transfer process, a piece of 0.06 mm thick single-sided sticky cellophane packaging
 413 tape was first carefully applied to fully cover the surface, where the Ag layer was stuck to
 414 the adhesive side without any residual air bubbles. An initial Si substrate removal process
 415 was performed in a HF + HNO₃ solution, mixed by aqueous HF (49% weight percentage)
 416 and HNO₃ solution (68% weight percentage) with a volume ratio of 10:1. The samples
 417 were pulled out and rinsed with DI water to stop the initial etching when the etchant starts
 418 to touch down on the polyimide layer. A XeF₂ dry etching process was then carried out to
 419 clean off the residue Si. In the final step, the polyimide protection layer was removed by
 420 O₂ plasma at 100 mTorr O₂ pressure and 200 W plasma power for ~ 11 mins.

421 Spectrally resolved measurements

422 Thermal spectral reflectance at normal incidence $r(\lambda, T)$ was characterized by a Nicolet
 423 iS50 FTIR spectrometer and Nicolet Continuum microscope over the spectrum 5 – 15
 424 μm. The objective lens was 32× with 0.65 numerical aperture. A blade aperture of 100
 425 μm × 100 μm was used to select the area of interest. All reflection spectra were
 426 normalized to the reflection spectrum of a 300 nm thick gold film. The temperature of the
 427 samples (ranging from 15 °C to 50 °C) was controlled by a customized closed-loop
 428 thermal stage, connected to a Lakeshore 321 temperature controller. Applying Kirchoff's
 429 law of radiation, thermal spectral emittance $\varepsilon(\lambda, T)$ was computed as
 430 $\varepsilon(\lambda, T) = a(\lambda, T) = 1 - r(\lambda, T)$ since the TARC was essentially opaque from 5 to 15 μm.

431 Near normal-hemispherical solar spectral reflectance $r(\lambda)$ was measured from 300 to
 432 2,500 nm with an Agilent Cary 5000 UV-vis-NIR spectrometer equipped with an Internal
 433 Diffuse Reflectance Accessory (DRA-2500), which collects both specular and diffuse
 434 reflections. Solar spectral absorptance was computed as $a(\lambda) = 1 - r(\lambda)$ since the film was
 435 essentially opaque to sunlight.

436 The solar absorptance A and sky-window thermal emittance ε_s can be calculated from the
 437 corresponding spectral data by:

$$438 \quad A = \left(\int_{0.3}^{2.5\mu\text{m}} I_s(\lambda) a(\lambda) d\lambda \right) / \left(\int_{0.3}^{2.5\mu\text{m}} I_s(\lambda) d\lambda \right)$$

$$439 \quad \varepsilon_s(T) = \left(\int_8^{13\mu\text{m}} B(\lambda) \varepsilon(\lambda, T) d\lambda \right) / \left(\int_8^{13\mu\text{m}} B(\lambda) d\lambda \right)$$

440 In which $I_s(\lambda)$ is the solar spectral intensity, and $B(\lambda)$ is the spectral radiance of black
 441 body.

442

443 **Thermal infrared imaging and analysis**

444 The TIR images were captured by a FLIR ONE infrared camera working at a wavelength
445 range of 8-13 μm . To minimize the reflection signals from the camera and the
446 surroundings, the default viewing angle was set as 15° instead of normal incident
447 direction, and the experiments were performed in an open-area, outdoor environment
448 under clear sky (cloud-free). When taking IR images, the camera measures the incident
449 thermal radiation, and then gives the temperature reading (T_{TIR}) assuming a constant
450 thermal emittance for the target (e.g., $\epsilon_0 = 0.90$, default setting of the camera).

451 **Simulation of device properties**

452 The spectral absorptance of TARC is numerically calculated using COMSOL
453 Multiphysics, with all the geometric parameters matching the original design. Material
454 properties in IR and visible ranges are from [1-3] and [4-6], respectively.

455 **Simulation of surface temperature**

456 The stabilized temperature of a surface (T_s) with given solar absorptance (A) and thermal
457 emittance (ϵ) was calculated based on adiabatic approximation, assuming negligible heat
458 transfer between the surface and the underlying structure. The key climate parameters for
459 a specific city or region, including air temperature (T_a), dew point temperature (T_d), wind
460 speed (v), solar radiance (I) and cloud coverage factor (CF) are obtained from the open
461 source data base⁷ using the TMY3 weather files. The thermal emittance of the TARC was
462 set at 0.20 for $T_s < 19^\circ\text{C}$ and 0.90 for $T_s > 27^\circ\text{C}$, and approximated by a linear
463 interpolation in the transition region ($27^\circ\text{C} > T_s > 19^\circ\text{C}$). Based on this setup, the all-
464 year-around temperature map (Fig. 4C) of TARC and of conventional materials with an
465 arbitrary combination of static A and ϵ were calculated and compared. More details of the
466 simulation can be found in the Supporting information.

467 **Projection of energy savings**

468 Rosado & Levinson⁸ simulated the annual space heating source energy savings ΔS_h
469 (typically negative) and the annual space cooling source energy savings ΔS_c (typically
470 positive) attained by increasing roof albedo for various categories and vintages of
471 buildings in 15 U.S. climates zones and 16 California climate zones. Note that ΔS_h and
472 ΔS_c are not directly presented in Rosado & Levinson but can be estimated from the
473 heating, cooling, and fan energy uses reported in that work, as described in SI Appendix
474 I.

475 Summing ΔS_h and ΔS_c yields the annual space-conditioning (heating + cooling) source
476 energy savings ΔS . We used U.S. cool-roof energy savings reported by Rosado &
477 Levinson and our own calculations of to the hourly roof surface temperature to regress
478 ΔS_h to reduction ΔD_h in annual average heating degrees D_h , and ΔS_c to reduction ΔD_c
479 in annual average cooling degrees D_c . These linear fits of the form $\Delta S_h = a_h \Delta D_h$ and
480 $\Delta S_c = a_c \Delta D_c$ yield $\Delta S = a_h \Delta D_h + a_c \Delta D_c$. Specifically, energy simulations for four
481 static roofing materials with $E=0.90$ and solar reflectance $R=0.10, 0.25, 0.40, \text{ or } 0.60$ (

482 $A=1-R=0.90, 0.75, 0.60$, or 0.40 were selected for the extraction of the coefficients α_h
483 and α_c using the material with $A = 0.90$ as the baseline.

484 To evaluate the potential space-conditioning source energy savings (SCSES) obtained by
485 using TARC instead of a reference roofing surface of static solar absorptance A_{ref} and
486 static thermal emittance ϵ_{ref} , we calculated in each city

487 $\Delta D_{h,\text{TARC}}(A_{\text{ref}}, \epsilon_{\text{ref}}) \equiv D_{h,\text{TARC}} - D_h(A_{\text{ref}}, \epsilon_{\text{ref}})$ and

488 $\Delta D_{c,\text{TARC}}(A_{\text{ref}}, \epsilon_{\text{ref}}) \equiv D_{c,\text{TARC}} - D_c(A_{\text{ref}}, \epsilon_{\text{ref}})$ varying A_{ref} and ϵ_{ref} from 0 to 1.00. We then
489 computed space-conditioning source energy savings

490 $\Delta S_{\text{TARC}}(A_{\text{ref}}, \epsilon_{\text{ref}}) \equiv \alpha_h \Delta D_{h,\text{TARC}}(A_{\text{ref}}, \epsilon_{\text{ref}}) + \alpha_c \Delta D_{c,\text{TARC}}(A_{\text{ref}}, \epsilon_{\text{ref}})$ over this space for each
491 building category and vintage of interest. The minimum $\Delta S_{\text{TARC}}(A_{\text{ref}}, \epsilon_{\text{ref}})$ (namely,
492 $\text{SCSES}_{\text{min}}$) for all possible existing roof coating properties is taken as the figure of merit
493 for each combination of local climate, building category and vintage group.
