ABSTRACT

Growing global water demand has brought desalination technologies to the forefront for freshwater production from non-traditional water sources. Among these, forward osmosis (FO) is a promising two-step desalination process (draw dilution and regeneration), but it is often overlooked due to the energetic requirements associated with draw regeneration. To address this limiting factor, we demonstrate FO desalination using thermally responsive ionic liquids (ILs) that are regenerated using a renewable energy input, *i.e.,* solar heat. To efficiently harness sunlight, a simple photonic heater converts incoming irradiation into infrared wavelengths that are directly absorbed by IL-water mixtures, thereby inducing phase separation to yield clean water. This approach is markedly

different as it uses radiative heating, a noncontact mode of heat transfer that couples to chemical functional groups within the IL for rapid energy transfer without a heat exchanger or secondary fluid. Overall, a solar-thermal separation efficiency of 50% is achieved under unconcentrated sunlight, which can be increased to 69% with thermal design. Successful desalination of produced water from oil wells in Southern California highlights the potential of solar powered IL-FO for energy-efficient and low cost desalination of complex brines for beneficial water reuse.

Keywords. Water-energy nexus, solar heat, stimuli-responsive materials, photo-thermal converter, produced water, wastewater treatment, renewable desalination, forward osmosis

INTRODUCTION

Global water demand is projected to increase by 55% over the next three decades owing to population growth, industrialization and climate change.[1-2] Concomitantly, large volumes of wastewater and concentrate are discharged from municipal, agricultural and industrial processes and their disposal has a significant environmental impact. These non-traditional brines are far more varied in their salinity and composition than seawater, thereby requiring new treatment methods beyond reverse osmosis (RO).[3] For example, produced waters, a byproduct of oil and gas extraction, represent an underutilized water resource – in the United States alone, nearly one million oil and gas wells generate ~2.4 billion gallons of water per day.[4] This water is typically disposed by deep-well injection, but increased environmental regulation and economic incentives are pushing industry to explore treatment options that convert produced water into a value added commodity, *e.g.* water for agricultural reuse.

45   Forward osmosis (FO) is a promising technology for desalination of non-traditional waters and

46   complex brines due to a number of intrinsic benefits over other technologies.[5] Recent literature

47   has shown that FO exhibits a higher fouling and scaling resistance relative to RO,[6-7] making it

48   suitable for variable water composition with minimal pre-treatment and membrane maintenance

49   and/or replacement.[8-9] In FO, the osmotic pressure difference between a saline solution (feed) and

50   a higher concentration solution (draw) causes water to spontaneously diffuse across a semi-

51   permeable membrane until osmotic equilibrium is attained by diluting the draw. Traditional draw

52   solutes comprise inorganic salts (*e.g.* sodium chloride) that generate large osmotic pressures at

53   high molar concentrations and yield favorable water fluxes. However, osmotic strength is not the

54   only factor for draw selection, as FO requires a second step to regenerate the draw and produce

55   clean water, which is very energy intensive. For example, sodium chloride can be recovered either

56   by supplementing FO with RO that requires more electrical energy than direct treatment (*i.e.,* RO

57   without FO) of the same feed,[10] or by evaporating water using thermal or membrane distillation

58   that is constrained by the large enthalpy of vaporization of water (~2400 J g^{-1}).[11-12] Such energy-

59   intensive processes for regeneration of inorganic draws have thus far precluded FO as a

60   competitive desalination technology. However, FO has the ability to utilize low-grade or waste

61   heat sources for draw regeneration, provided that a suitable draw solution is used. Thus, identifying

62   a chemistry that satisfies both criteria of high osmotic pressure for water flux, as well as an energy-

63   efficient regeneration mechanism represents a key challenge.

64   A novel class of draw solute materials are thermo-responsive ionic liquids (ILs), pioneered by Ohno

65   and coworkers,[13-14] which were originally developed for protein extraction from aqueous solutions.

66   The inherent ionic state of these organic salts generates high osmotic pressures that enables their

67   use as draws for FO.[15-16] Furthermore, aqueous mixtures of these ILs exhibit a liquid-liquid phase

68 separation when heated above a critical temperature (lower critical solution temperature or LCST)

69 owing to a negative entropy of mixing. The energy required for separation of water from ILs (*i.e.,*

70 enthalpy of de-mixing) is approximately 10 J g^{-1}, which is orders of magnitude lower than the first

71 order phase transition of water that is prevalent in traditional thermal regeneration (2400 J g^{-1}).

72 This liquid-liquid phase separation is also much simpler than other draws used in FO with

73 solubility-dependent regeneration mechanisms that evolve gases,[17-18]and it occurs at relatively low

74 temperatures <50 °C and at atmospheric pressure. As a result, these thermo-responsive draw

75 solutions can be coupled with a low-grade source such as solar-thermal energy, which in turn

76 significantly reduces the carbon footprint and cost of water treatment.[2] Despite this, IL-water phase

77 separation has not received much attention, with literature being limited to heating a beaker

78 immersed in a water bath or a hot plate for draw regeneration.[16, 19] Furthermore, IL-based FO has

79 only been tested with simple NaCl feed solutions, and the use of custom-synthesized membranes

80 have limited its practical use.[15-16]

81   In this work, we demonstrate a proof-of-concept comprising LCST-type ILs as draw solutions

82 for FO desalination coupled to a solar energy harvester that provides heat for regeneration. Solar

83 energy can either be harnessed indirectly (absorbed by a solid surface or a heat transfer fluid in a

84 conventional solar collector) or directly *via* absorption by the liquid. In the first case, a heat

85 exchanger may be required to transfer heat to the draw, which not only has surfaces that are

86 susceptible to corrosion over time, but also adds to the overall system cost. In contrast, direct

87 absorption of energy by the liquid is an efficient and noncontact mode of heating that depends

88 predominantly on the spectral optical properties of IL-water mixtures, which have not been

89 measured to date. Herein, we demonstrate the feasibility of this new approach using a photo-

90 thermal device (*aka* photonic heater) that enables radiative heating. The overarching goal is the

91   development of a continuous process in which the thermo-responsive IL effectively draws water

92   in an FO membrane unit and then undergoes regeneration in a thermal separator unit, thereby

93   providing high quality freshwater (total dissolved solids, TDS <500 ppm) with minimal electrical

94   energy input, as shown in Fig. 1.
95

96   **Fig. 1. An illustration of the proposed solar-FO desalination system**. A contaminated feed *(e.g.*

97   *produced water from oil and gas extraction)* undergoes pre-treatment and enters an FO membrane module

98   in which the IL draw solute (with a higher concentration compared to the feed) causes water molecules

99   from the feed to diffuse through the membrane under a natural osmotic gradient. The diluted draw then

100   flows into a thermal separator in which thermal emission from the photonic heater illuminated by sunlight

101   causes a rise in its temperature. Liquid-liquid phase separation occurs as the temperature increase above

102   LCST, with the denser IL-rich phase settling at the bottom while the water-rich phase is on top. The former

103   is recycled as the draw for FO, while the water-rich phase with residual IL content undergoes a low pressure

104   nanofiltration polishing step to attain high quality product water.

105

106   **MATERIALS AND METHODS**

107   Various thermo-responsive ILs have been identified in literature for different applications, but

108   not all are suitable for solar-FO desalination. With multiple properties to be optimized and many

5

109   potential IL chemistries, the analytical hierarchy process[20] was used to down-select suitable ILs.

110   Specifically, ILs with tetrabutylphosphonium (P_{4444}^+) as the cation were chosen as its

111   amphiphilicity results in LCST behavior with a variety of anions; with 2,4-dimethylbenzene

112   sulfonate (P_{4444}DMBS or DMBS) and trifluoroacetate (P_{4444}TFA or TFA) emerging as ideal

113   candidate materials (table S1).

114   **Synthesis of Ionic Liquids.** P_{4444}DMBS was synthesized using a neutralization reaction.[15] The

115   starting materials were tetrabutylphosphonium hydroxide (TBPH) and 2,4-dimethylbenzene-

116   sulfonic acid (TCI America). Both reagents were mixed with water in a 1:1 molar ratio, with a

117   slight excess of the sulfonic acid and stirred at room temperature for 24 hours. The solution was

118   then added to a separatory funnel and extracted with dichloromethane (DCM); this step was

119   repeated three times. The organic phase was collected and washed with water three times and then

120   transferred to a rotary evaporator in order to remove DCM from the IL. The resultant IL was stored

121   in a vacuum oven at 90 °C for 48 hours to remove residual water. ^{1}H-NMR spectra of P_{4444}DMBS

122   in d-DMSO (δ/ppm relative to TMS) showed: δ = 0.81-0.93 (12H; a), 1.29-1.54 (16H; b, c), 2.05-

123   2.18 (8H, d), 2.18 (3H, g), 2.45 (3H, e), 6.78-6.94 (2H; f, h), 7.52-7.61 (1H, i); see fig. S1A.

124   P_{4444}TFA was also prepared using a neutralization reaction between TBPH and trifluoroacetic acid

125   (TCI America). TBPH was added to water and stirred, and trifluoroacetic acid was added drop-

126   wise to this solution over several hours and mixed at room temperature for 24 hours. The solution

127   was then worked up using DCM extraction and dried in the vacuum oven, as described for DMBS.

128   ^{1}H-NMR was performed (DMSO, δ/ppm relative to TMS): δ = 0.78-0.98 (3H; a), 1.25-1.51 (4H;

129   b,), 2.03-2.19 (2H, c); see fig. S1B.

130   **Characterization of Ionic Liquid Solutions.** Relevant solution properties of aqueous

131   mixtures of ILs were characterized as a function of concentration.

132   Phase diagram: To obtain the LCST of the ionic liquids, UV-Vis spectroscopy was performed

133   (Agilent Technologies). Cloud point measurements[21] were used to identify the temperature at

134   which the transmittance drops from 100 to 0%, *i.e.,* the point where phase separation is initiated.

135   (fig. S2). Differential scanning calorimetry (DSC) was performed to verify the temperature at

136   which phase separation occurs and to measure the enthalpy of transition (fig. S3).

137   Viscosity: Aqueous IL solutions were measured using an HR-2 rheometer (Discovery Series

138   from TA Instruments) with a parallel plate accessory at a shear rate of 100 Hz. Measurements at

139   25 °C of 40 wt % P_{4444}DMBS confirmed the Newtonian behavior for this class of phosphonium

140   ionic liquids (fig. S4). A thermostatted Peltier accessory was used to measure temperature-

141   dependent viscosity, with a resolution of 0.1 °C.

142   Osmotic pressure: To evaluate the osmotic strength, osmolality was measured using a Wescor

143   5600XR vapor pressure osmometer (Thermo Fisher Scientific). Osmolality was converted to an

144   approximate osmotic pressure, π as: $\pi = m\rho RT$, m is the measured osmolality, ρ is the density of

145   the mixture (approximated as the density of water), R is the molar gas constant, and T is the

146   absolute temperature.

147   Optical properties: UV-Vis spectroscopy and FTIR-ATR (Thermo Electron Nicolet 5700)

148   were used to measure the optical properties of pure ILs over a wide wavelength range. Optical

149   properties of IL-water mixtures in the infrared region were measured in transmission mode using

150   an Omni-Cell liquid accessory (Specac) with KRS-5 windows and a fixed path length of 50 μm

151   (fig. S14). Optical properties of the photonic heater comprising a selective solar absorber (TiNOX,

152   Almeco Group) and blackbody emitter (Zynolyte hi-temp paint, Aervoe) were also measured using

153   an FTIR with an integrating sphere accessory (Pike Technologies Mid-IR IntegratIR). As the

154   samples were non-transmitting, absorptance was calculated as unity minus reflectance (fig. S15).

Membrane Characterization. An FEI Phenom tabletop Scanning Electron Microscope (SEM) was used to obtain high resolution images of new and used membranes post-FO experiments with ionic liquids and produced water samples, and EDX maps of the active and support layer of the membrane were generated (fig. S11-S13).

Forward Osmosis Draw Dilution Process. FO experiments were performed in a lab-scale setup comprising a commercial acrylic cross-flow cell (Sterlitech Corporation) at 25 °C using a thin film composite membrane (Porifera Inc.). Feed and draw solutions were pumped in counter-current mode at 200 mL min^{-1} (crossflow velocity ~3 cm s^{-1}). The feed was placed on an analytical balance to measure mass loss over time ($\Delta m/\Delta t$), and water flux was calculated as: $J_w = \frac{\Delta m/\rho}{A_m \Delta t}$, where A_m is the effective membrane area (fig. S9). Active layer facing the draw resulted in higher water fluxes, and this configuration was used for all experiments. The reverse solute flux was obtained using a conductivity probe (for NaCl) and by performing a Total Organic Carbon analysis (for ILs) to measure changes in feed concentration over time ($\Delta C/\Delta t$) as: $J_s = \frac{\Delta C \times \Delta m/\rho}{A_m \Delta t}$. Long duration experiments were conducted for 16 hours with continuous draw dilution (fig. S10B).

Solar-Thermal Draw Regeneration Process. A solar simulator (Newport, 94081A) with an optical filter for AM 1.5G spectrum was used. A power meter and thermopile detector (Newport, 919P-030-18) were used to measure the incoming solar flux (1000 W m^{-2}) at the same location as the diluted draw. The draw was placed in an acrylic vessel, which comprises an inner pocket (square with a side length of 3.5 cm and a 5 cm depth) coated in reflective foil. The inner pocket is surrounded by a 2 cm thick acrylic wall on all sides to minimize thermal losses. K-type thermocouples were placed at 0.5 cm and 4 cm below the liquid surface to record the temperature at the top (T_{top}) and bottom of the vessel (T_{bottom}), respectively. The photonic heater was placed ~4 mm above the liquid to ensure a high view factor for noncontact radiative heat transfer. A K-type

178 thermocouple on the surface of the photonic heater measured its temperature to estimate the

179 blackbody emissive power. The thermocouples were connected to a data logger (Pico

180 Technologies, USB TC-08).

181 **Nanofiltration Post-treatment Process.** A dead-end filtration stainless steel stirred cell was

182 used (Sterlitech Corporation) with a 47 mm diameter membrane disc (Dow Filmtec). The NF270

183 polyamide membrane with a molecular weight cutoff of 200-400 Da was chosen as it is designed

184 to remove organics, thereby making it suitable for rejection of ionic liquids. To minimize

185 concentration polarization at the membrane surface, a PTFE-coated magnetic stir bar was used at

186 200 rpm. The cell was connected to a nitrogen cylinder using a pressure gauge and the resulting

187 water flux, J_w was obtained by measuring the change in permeate volume over time.

188 **Evaluation of Non-Ideal Mixture Behavior *via* Molecular Dynamics (MD) Simulations.**

189 All-atom AMBER force fields for potential energy, U were used in the MD simulation of this

190 system.

$$U_{potential} = \sum_{i>j} \left[4\varepsilon_{ij} \left\{ \left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}} \right)^{6} \right\} + \frac{q_i q_j}{4\pi\varepsilon_0 \varepsilon_r r_{ij}} \right] + \sum_{bonds} K_r (r-r_0)^2 + \sum_{angles} K_\theta (\theta - \theta_0)^2$$
$$+ \sum_{torsions} \frac{K_\varphi}{2} \left\{ 1 + \cos(n\phi - \gamma) \right\}$$

(1)

191 The first term describes the non-bonded interactions including Van der Waals as the Lennard-

192 Jones 12-6 form and Coulombic forces from atom-centered partial charges. The following terms

193 in the potential energy equation represent, respectively, bonds, angles and torsional interactions.

194 The force field parameters of atomistic P_{4444} cation, DMBS anion and TFA anion were developed

195 in previous work[22-24] (tables S3-S6). The TIP4P water model[25] was employed for water molecules,

196 which depicts the dynamic and structural properties of liquid water. The VdW interaction

197 parameters between unlike atoms were obtained from the Lorentz−Berthelot combining rule. Non-

9

198 bonded interactions separated by exactly three consecutive bonds (1−4 interactions) were reduced

199 by related scaling factors,[26-27] which were optimized as 0.50 for VdW interactions and 0.83 for

200 electrostatic interactions, respectively. The schematic molecular structures and partial charges of

201 the P_{4444} cation, DMBS anion, TFA anion and water molecule of the TIP4P water model are

202 presented in fig. S5. Atomic charges for DMBS anion were calculated using a web-based

203 calculator, Atomic Charge Calculator, via the Electronegativity Equalization Method (EEM).[28]

204 MD simulation was performed using LAMMPS package with standard 3D periodic boundary

205 conditions. The number of initially displayed ion pairs and water molecules to match the

206 concentration cases is summarized in table S7. The non-bonded interactions were cut off at 15 Å

207 while the particle-particle particle-mesh solver[29] was applied to treat the long-range electrostatic

208 interactions. All simulations were carried out at isothermal-isobaric conditions, at 25 °C and

209 ambient pressure, in the Nose-Hoover NPT ensemble with time coupling constants of 100 and

210 1000 fs, respectively. After initial relaxations with short time steps and an equilibration with long

211 time steps, at least 6 ns simulation of the ensemble were performed with a fixed time step of 1fs.

212 Atomic simulation trajectory or RDFs were recorded at an interval of 1.5 ps for post-analysis.

213 **RESULTS AND DISCUSSION**

214   **Solution Properties of Thermo-Responsive ILs.** The binary phase diagram and critical

215 transition temperature of both DMBS and TFA are shown in Fig. 2A. DMBS displays a broad

216 binodal phase curve, with an LCST of 36 °C at a concentration of 40 wt%, while the TFA phase

217 curve is symmetric with an LCST of 31 °C at that concentration. The curve width dictates the

218 effectiveness of phase separation upon heating - at a temperature of 55 °C, the 40 wt% DMBS

219 separates into a concentrated IL-rich phase >80 wt%, while TFA at the same concentration and

220 temperature separates into an IL-rich phase of ~70 wt% (confirmed by NMR analysis). Thus, the

221 draw solutions should be heated not just to their LCST, but to temperatures ~20 °C higher in order

222 to be regenerated and reused in a subsequent FO process, while the water-rich phase contains <10

223 wt% IL. The enthalpy of separation or de-mixing, ΔH_{mix}, for both ILs at a concentration of 50 wt%

224 was obtained as 2-5 J g^{-1} of the mixture (fig. S3). This liquid-liquid separation enthalpy is 1000x

225 lower than the enthalpy of liquid-vapor phase change, which highlights advantages of using these

226 ILs that undergo a reversible phase separation with water.

227   The viscosity of DMBS and TFA solutions are shown in Fig. 2B, as viscous draws can cause

228 concentration polarization that adversely impacts water flux.[30] At concentrations <30 wt% the

229 mixture viscosity is close to that of water (~1 mPa-s) but then increases with concentration, likely

230 due to molecular interactions (*e.g.* ion pairing and/or molecular aggregation) at non-dilute

231 concentrations.[31] These molecular interactions also result in an unusual dependence of viscosity

232 on temperature: as the IL-water mixture is heated above room temperature, its viscosity decreases

233 according to the well-known Arrhenius relationship. However, as the critical temperature for a

234 given concentration is approached, viscosity increases sharply, indicating structural reorganization

235 and formation of aggregates in solution that leads to phase separation. With further increase in

236 temperature, viscosity decreases again as the phase-separated water-rich layer resembles a dilute

237 mixture (fig. S4). Similar temperature-dependent viscosity trends have been reported in binary

238 mixtures of water and imidazolium-based ILs that do not display LCST behavior, as well as in

239 LCST-type polymers or polyelectrolytes in which aggregation increases the effective molecular

240 weight, thereby showing a sharp increase in viscosity with temperature.[32-33] In contrast, the lower

241 viscosity of the two down-selected ILs (at least by a factor of three) at all concentrations, as well

242 as their weaker temperature dependence around the critical temperature is more suitable for FO.

243   To evaluate the ability of ILs as draw solutes to desalinate saline feeds, their osmotic strength

244   was measured at different concentrations. We note that these measurements were performed at 25

245   °C (temperature at which FO dilution occurs), which is in contrast with literature measurements

246   based on freezing point that over-predicts osmotic strength as the physical state of the mixture and

247   thermal interactions are altered at low temperatures.[16] Fig. 2C shows the osmolality of both ILs,

248   which provides a measure of ions dissolved in solution at a given concentration, and this is

249   converted into an approximate osmotic pressure. The osmotic pressure of both ILs can be tuned

250   by changing the mixture concentration, rendering them suitable for salinities ranging from brackish

251   water to produced water. At low concentrations <10 wt%, the osmolality of both DMBS and TFA

252   increase linearly, indicating complete dissociation into constituent ions as expected in a dilute

253   mixture. However, at intermediate concentrations ~20-50 wt%, both ILs appear to have a near-

254   constant osmolality, which increases dramatically upon further increase in concentration >60 wt%.

255

Fig. 2. Characterization of aqueous mixtures of DMBS (in blue) and TFA (in red) as a function of

their concentration in water. (A) Binodal phase diagram that shows the LCST **(B)** Viscosity. **(C)**

Osmolality and calculated osmotic pressure, with dilute mixtures shown in the inset.

259   To understand this unusual behavior, osmolality was plotted as a function of mixture molality

260   and compared with an ideal solute like NaCl. As shown in Fig. 3A, above ~0.3 mol kg^{-1}, osmotic

261   pressure generated by IL ions in solution deviates significantly from NaCl dissolved in water. To

262   provide insight on this, Molecular Dynamics (MD) simulations were performed, in which the

263   parameter of interest is the number of water molecules in the first hydration shell of the IL that is

264   known to be a prerequisite for LCST behavior (Supplementary Note S2).[31] The first peak of the

265   radial distribution function between atoms in the IL and water provides information on atoms that

266   constitute hydration shells and their radius – the central P atom in the P_{4444} cation, S atom and

267   benzene ring in the DMBS anion, and the C2 atom in the TFA anion were pivots for hydration

268   shells (fig. S6-S7). The inset in Fig. 3B provides a pictorial representation for DMBS showing the

269   distribution of water molecules *(i)* exclusively within the coordination shell of a single ion, *(ii)*

270   shared between multiple ions, or *(iii)* outside the first coordination shell of all ions. As the IL

271   concentration increases, the number of water molecules inside the first coordination shell per ion

272   pair decreases (Fig. 3B line graph). Furthermore, the ratio of water molecules contributing to the

273   first coordination shell of multiple ions increases at higher IL concentrations (Fig. 3B area graph).

274   In other words, not all individual ions are hydrated due to an insufficient number of water

275   molecules at these high concentrations of DMBS, resulting in ion aggregation and shared water

276   molecules between multiple ions. The following hypothesis was tested: to contribute to osmotic

277   strength, a certain number of water molecules are required at a given concentration for IL

278   dissociation into its constituent ions (*i.e.,* one cation and one anion per IL molecule). Single cation

279   and anion simulations were performed to calculate the number of water molecules in the ions' first

280   coordination shell that ensure dissociation (fig. S8). Given that water molecules are shared by

281   multiple ions at some concentrations, two definitions of free ion were evaluated: shared water

282   molecules solvate all ions, or only solvate the nearest ion. Simulation results for both ionic liquids

283   indicate that the latter definition dominates, *i.e.,* shared water molecules contribute only to

284   solvating the nearest ion, as this correlates well with experimental data shown in Fig. 3C for

285   DMBS. The apparent free ion ratio is defined as the ratio of measured osmolality to that predicted

286   by van't Hoff theory for an ideal solute that dissociates into two ions (*i.e.,* like NaCl) in solution.

287   This suggests that a number of IL ions in solution are clustered, with shared hydration shells

288   solvating only the nearest ion which hinders other ions from contributing to osmotic strength. At

289   all concentrations, TFA has a larger free ion ratio than DMBS as shown in Fig. 3D, resulting in a

290   higher osmolality.
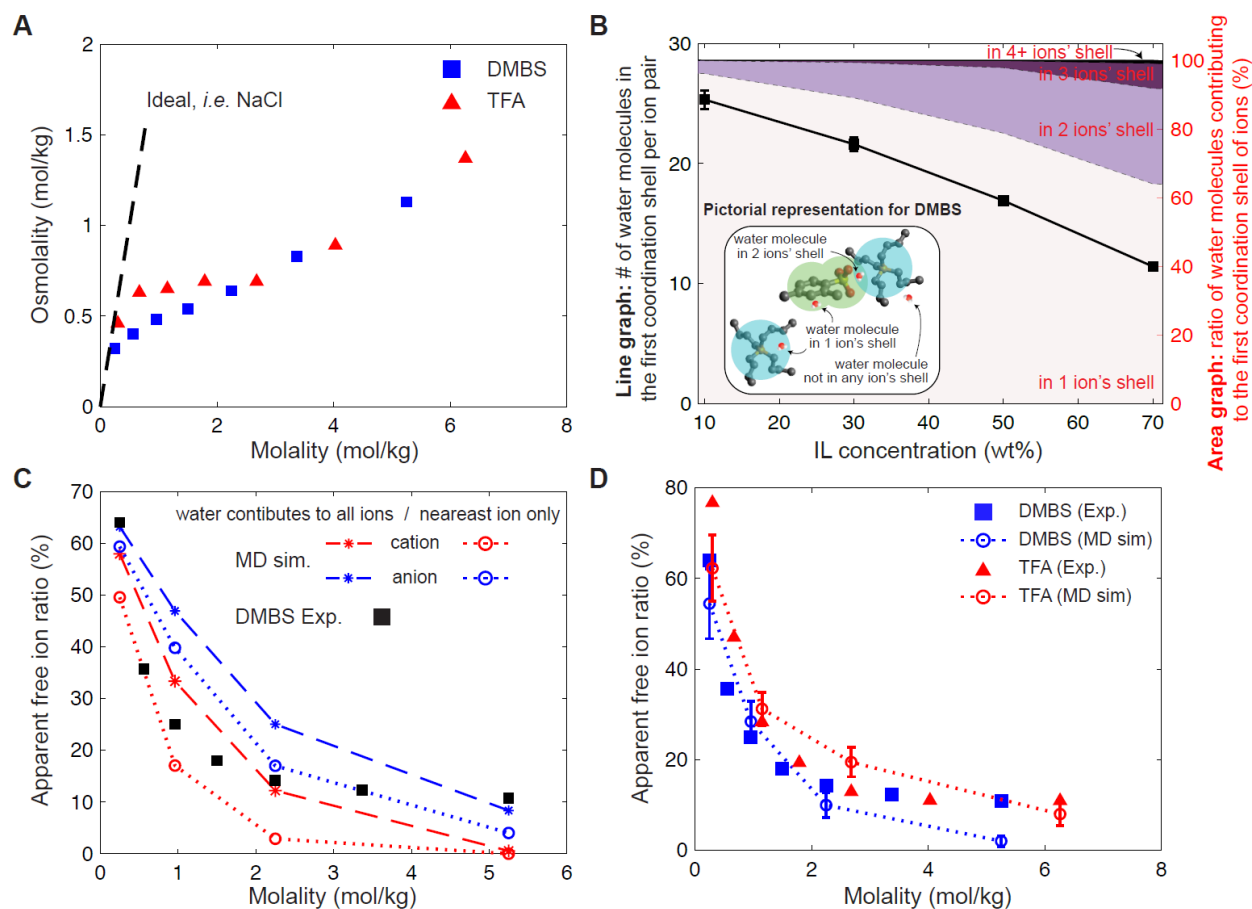

291

292   **Fig. 3. Concentration dependence of osmolality showing deviations from ideal mixtures. (A)**

293   Osmolality measured as a function of molality using a vapor pressure method showing differences between

294   ILs and NaCl in solution. **(B)** Molecular dynamics simulation showing the number of water molecules in the

295   first coordination shell per ion pair of DMBS (line graph) and the ratio of water molecules contributing to the

296   first coordination shell of multiple ions (area graph) as a function of IL concentration **(C)** Molecular dynamics

297   simulation showing the apparent free cation and anion ratio for DMBS compared to experimental data under

298   two assumptions. **(D)** Molecular dynamics simulation showing the apparent free ion ratio for DMBS (in blue)

299   and TFA (in red) compared to experimental data under the hypothesis that water molecules contribute to

300   the osmotic strength of the nearest ion only.

301   The osmolality data and MD simulations reveal for the first time, the existence of a critical

302   concentration that is unique to each IL. This concentration represents the point at which IL-water

303   mixtures deviate from ideality and behave like complex (*i.e.,* non-dilute) fluids with ion pairing

304   that results in a lower osmotic pressure and adversely impacts FO water flux. We have previously

305   shown that ion aggregation is dependent on temperature and is an intermediate step towards LCST-

306   type phase separation,[31] but the occurrence of aggregation at room temperature is revealed for the

307   first time through these MD simulations. This indicates an opportunity to develop new IL

308   chemistries that exhibit higher critical concentrations for aggregation (*i.e.,* less ion pairing like

309   TFA compared to DMBS) to ensure higher osmotic pressures.

310   **Forward Osmosis Desalination of Produced Water Feeds.** A lab-scale FO setup was

311   designed to test the performance of the two IL draw solutions, as shown in Fig. 4A. Commercially

312   available FO membranes are benchmarked against traditional inorganic draw solutions like NaCl

313   using water flux (in $L\,m^{-2}\,h^{-1}$ or LMH) and reverse solute flux, RSF (in $g\,m^{-2}\,h^{-1}$ or gMH) with a

314   deionized water feed. RSF is a measure of draw solute back-diffusion through the membrane that

315   gradually lowers draw concentration (and increases feed concentration), thereby decreasing the

316   water flux and requiring periodic draw replenishment that increases operational costs.[34] Given the

317   differences in solution properties of ILs and simple salts like NaCl, the selectivity of commercial

318   FO membranes with ILs was tested. Fig. 4B displays the measured water flux using 70 wt% DMBS

319   and TFA draws with a DI water feed, and the corresponding RSF. The membrane selectivity, γ is

320   obtained by dividing reverse solute flux by the water flux across the membrane.[35] DMBS and TFA

321   IL-based draws show γ values of 0.18 and 0.05 $g\,L^{-1}$, respectively, which are lower than NaCl (0.7

322   g L^{-1}) and also significantly lower than other thermally regenerated draws such as ammonia-carbon

323   dioxide (γ >2 g L^{-1}).[35] This is attributed to the larger size of the IL molecules (12.5 Å unhydrated)

324   compared to NaCl (5.6 Å unhydrated), which hinders back diffusion of the IL through the FO

325   membrane. While DMBS and TFA IL-based draws exhibit low RSFs relative to other FO draws,

326   this draw leakage will necessitate periodic draw replenishment over time. Efforts directed at

327   optimizing flow parameters and membrane design will aid in reducing RSF values further. These

328   results confirm that commercial membranes used in this work show a high selectivity with organic

329   solutes, indicating that the selected LCST-type draws are suitable for FO.

330   To evaluate the use of ILs in a practical application, real produced water feeds were obtained

331   from two different oil fields operated by the California Resources Corporation (Elk Hills and South

332   Mountain) in southern California (table S2). Based on the measured osmolality of produced water

333   samples, 70 wt% TFA and 70 wt% DMBS draw solutions were selected. Fig. 4C shows the

334   desalination performance of both IL-based draws, with TFA yielding a higher water flux owing to

335   its higher osmolality and lower viscosity when compared to DMBS at the same concentration. We

336   note that the flux values can be increased significantly by lowering mass transport resistances, *e.g.*

337   higher cross-flow velocities (compared to ~3 cm s^{-1} used in these experiments) and well-designed

338   hydrodynamics in custom-designed cells (using spacers and shims), and should be considered to

339   realize the full potential of IL chemistries as draws in FO.

340

16
Fig. 4. Lab-scale forward osmosis experiments. (A) Schematic of the experimental FO setup to evaluate the water flux for different feed and draw solutions. The membrane is oriented such that the active layer faces the draw in all experiments. **(B)** Measured water flux (LMH) and reverse solute flux (gMH) when using IL-based draw solutes, 70% DMBS and 70% TFA, with a DI water feed; γ represents the membrane selectivity and is obtained by dividing the solute flux by the water flux. **(C)** Measured water flux using real produced water samples (Elk Hills, South Mountain) with 70% DMBS and 70% TFA as draw solutes. The inset shows the feed samples used in the FO process (courtesy of the California Resources Corporation).

To assess the compatibility of commercial membranes with IL draws and produced water feeds, SEM-EDX analysis was performed. The structural (fig. S11) and chemical (fig. S13) composition of the membrane remain unchanged, thereby confirming that commercial FO membranes can be reused after rinsing or backwashing with DI water, with no significant decrease in flux over multiple runs with the ILs and produced water feeds (table S8).

Draw Regeneration and Clean Water Production using Solar Heat. After the FO step, diluted draw solutions ~40-50 wt% (based on NMR analysis) must undergo phase separation by heating above the LCST. Solar energy is used as the heat source, with the goal of achieving direct absorption of radiation by the liquid to increase its temperature. This noncontact mode of heating proceeds *via* thermal radiation and has advantages over conventional photo-thermal materials and surfaces that heat the liquid *via* convection and/or conduction, which is limited to lower temperatures and is susceptible to corrosion or degradation over time.[36-37] However, pure ILs are transparent across the solar spectrum (fig. S14A) and instead show multiple absorption bands in the infrared that correspond to vibration modes of constituent chemical functional groups (Supplementary Note S4). Given that water's O-H bond strongly absorbs at *ca*. 2.8 μm, it is expected that IL-water mixtures will also absorb across the IR region. Fig. 5A shows the infrared transmittance of 50 wt% DMBS and TFA; the transmittance of DI water is also measured and

17

365 matches literature data.[38] For both mixtures, strong absorption in the short- (2.5-3 µm) and mid-

366 infrared (6-8 µm) wavelength range corresponds to vibrational and rotational modes of the pure

367 IL molecules (fig. S14B). Thus, by converting solar energy into infrared radiation, direct

368 absorption by the liquid can induce effective phase separation, *i.e.,* draw regeneration. This is

369 achieved using a photonic heater that absorbs solar irradiation and re-emits in the mid-infrared

370 region that overlaps with the absorption spectrum of aqueous ILs; mid-IR wavelengths correspond

371 to thermal emission from a blackbody heated to temperatures ~100 °C.

372 To demonstrate the feasibility of this new draw regeneration mechanism at the lab-scale,

373 diluted draws of TFA and DMBS from FO desalination of produced water feeds were each tested

374 with the photonic heater (comprising a selective solar absorber and a blackbody emitter, fig. S15),

375 as shown in Fig. 5B. Under an illumination of 1000 W m^{-2} (one-sun solar flux), the absorber

376 temperature rapidly increases to 80 °C as incident sunlight is converted into thermal radiative

377 energy. This heat is transferred to the emitter, causing it to emit as a blackbody at a peak

378 wavelength of ~8 µm matching the spectral absorption profile of IL-water mixtures (fig. S16B).

379 This radiative coupling allows for direct absorption of thermal emission by the underlying liquid,

380 resulting in a temperature increase well-above the LCST, as shown in Fig. 5C. To quantify the

381 extent of phase separation, aliquots of the heated mixture were analyzed for their composition,

382 where the top layer comprises the water-rich phase and bottom layer is the IL-rich phase as shown

383 Fig. 5D. Residual amounts of IL ~10 wt% in the water-rich phase can be removed by a

384 nanofiltration (NF) post-treatment process with a small external pressure input, and the IL-rich

385 phase >65 wt% can be reused as draw in the FO module, as shown in Fig. 5E. We note that an NF

386 polishing step is required to obtain high purity water (<2 wt% IL) as heating alone does not remove

387 IL aggregates from water as shown in the MD simulations; new IL chemistries that exhibit a very

388 broad phase diagram would be able to eliminate this step, as would end-use applications that do

389 not require ultraclean product water. The pressure required for NF is dictated by the osmotic

390 pressure of the water-rich phase, which was measured in Fig. 2C as ~10 bar, and hence a pressure

391 of 12 bar was applied. Analysis of the NF permeate reveals near-perfect rejection of both ILs, with

392 a water content of 100 wt% for DMBS (owing to its larger size) and 98.8 wt% for TFA, as shown

393 in Fig. 5F. High purity product water is obtained post NF, with a TDS <500 ppm for both IL draws

394 (220 ppm for DMBS permeate and 430 ppm for TFA permeate) that satisfies the maximum

395 contamination level target set by the U.S. Environmental Protection Agency for drinking water

396 (for full water analysis assessment see table S2).[39] These experiments are the first demonstration

397 of utilizing solar heat for regeneration of IL-based draws after produced water desalination,

398 yielding high-quality water for beneficial reuse.
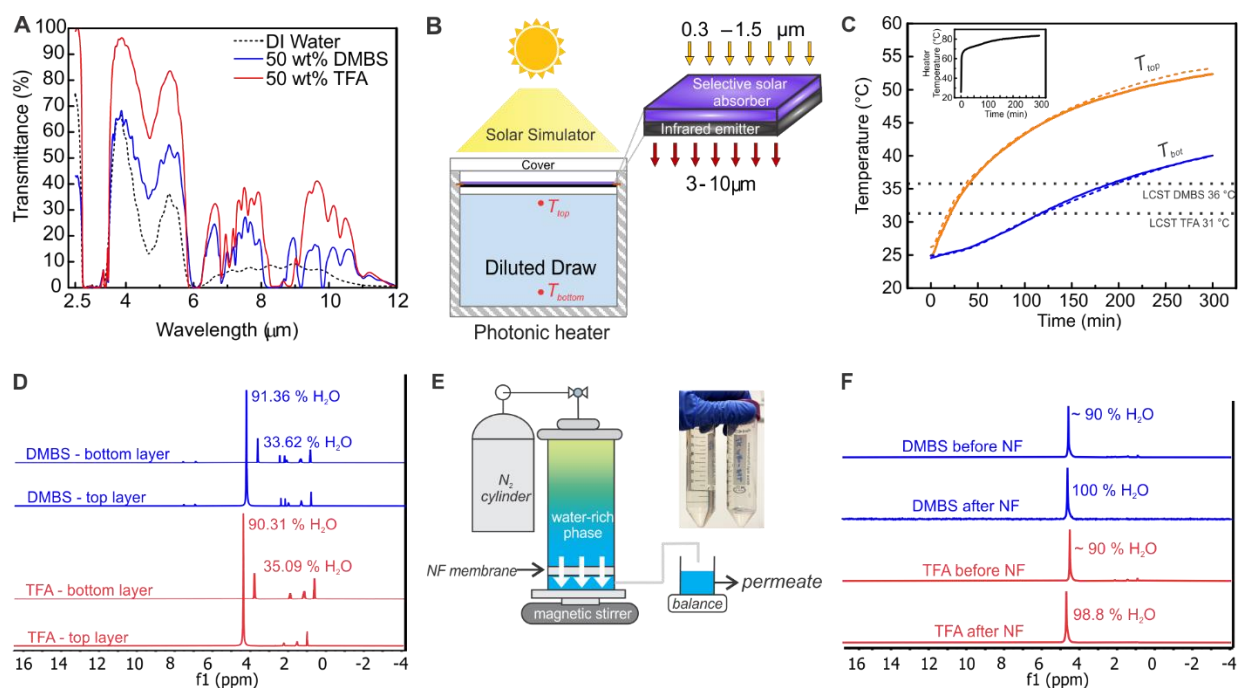

399

400 **Fig. 5. Experimental testing of draw regeneration using a photonic heater that converts solar energy**

401 **into infrared radiation for heating above the LCST**. **(A)** Optical transmittance of aqueous IL mixtures

402 measured using a 50 µm spacer or path length showing absorption at mid-infrared wavelengths; for larger

403   path lengths ~1 mm (liquid layer thickness), there is complete absorption across the entire IR range. **(B)**

404   Schematic of a lab-scale setup for radiative heating of diluted IL mixtures using a photo-thermal converter

405   under a solar simulator output of 1000 W m^{-2}. **(C)** Temperature evolution of the diluted DMBS (dashed line)

406   and TFA (solid line) solution, with phase separation caused by radiative heating above their respective

407   LCST; inset shows the temperature profile of the photonic heater. **(D)** ^{1}H-NMR analysis of the water content

408   of the phase separated layers due to solar heating, with the water-rich layer on top of the IL-rich layer. **(E)**

409   Lab-scale setup of dead-end nanofiltration for removal of residual IL from the water-rich phase after solar

410   separation; inset shows the NF permeate after solar-FO of produced water feed (South Mountain) with 70

411   wt% DMBS and TFA draws. **(F)** ^{1}H-NMR analysis of the water content of permeate from nanofiltration

412   showing near-perfect rejection of ILs at an applied pressure of 12 bar.

413   Phase separation experiments under realistic conditions of varying solar flux were performed

414   under natural sunlight in Berkeley, California (Supplementary Note S6). These results confirm that

415   temperatures above LCST are attained to induce phase separation of water from the IL (fig. S22),

416   thereby demonstrating the feasibility of such a solar-IL-FO desalination system for regions that

417   have a solar resource ~5 kWh m^{-2} day^{-1} (*e.g.* western United States).

418   **Energy Consumption of Lab Prototype.** One important metric for solar-IL-FO is the specific

419   energy consumption of the overall desalination process. As shown in Fig. 1, an integrated solar-

420   FO system comprises draw dilution in the FO module (commercially available from different

421   vendors) and draw regeneration in the thermal separator (custom designed based on draw solution

422   properties). Given that the FO step is spontaneous, the only energy input required at this stage is

423   electricity for circulating feed and draw solutions, estimated as 0.5 - 1 kWh$_e$ m^{-3} (kWh electric)

424   based on previous studies[40] and viscosity of the IL draws. If high-quality product water is desired,

425   a nanofiltration post-treatment can be used to reject residual ILs using electricity. For the

426   experimental conditions shown in Fig. 5, NF with an applied pressure of 12 bar consumes ~0.3

427   kWh$_e$ m^{-3} (Supplementary Note S7), which yields an overall electrical energy consumption of

428 <1.5_e kWh m^{-3}. Such a small value is because the primary energy consumption in a solar-IL-FO

429 system is thermal energy required for phase separation of the IL-water mixture by heating. Based

430 on the enthalpy of mixing/de-mixing of the diluted draw (ΔH_{mix}), this is estimated to be 2.7 kWh$_t$

431 m^{-3} (kWh thermal). Additional energy ~32 kWh$_t$ m^{-3} in the form of sensible heat is required to

432 attain temperatures above LCST for phase separation (52 °C in this case); this results in a total

433 thermal energy consumption of 35 kWh$_t$ m^{-3} for the experimental conditions shown in Fig. 5C,

434 which is provided by a constant solar input of 1000 W m^{-2}. A major portion of this thermal energy

435 consumption is from sensible heating, which is stored in the liquid and can be reused to pre-heat

436 diluted draw before it enters the thermal separator. Taking this into account, the specific thermal

437 energy consumption is calculated to be 9 kWh$_t$ m^{-3} (Supplementary Note S7). This is significantly

438 lower than conventional thermal desalination processes that require 660 kWh$_t$ m^{-3} for evaporating

439 water, as well as highly efficient configurations of multi-effect distillation (MED) with heat

440 recovery that lowers the energy consumption to ~70 kWh$_t$ m^{-3}.[11-12] This highlights the advantage

441 of using draws with novel phase transitions, such as the reversible LCST behavior in thermo-

442 responsive ILs. The energy consumption (both thermal and electrical) is dependent on the diurnal

443 nature of solar irradiation which changes the temperatures of the photonic heater and diluted draw

444 (table S9).

445 **Solar-thermal Efficiency for phase separation.** Another important metric for solar-IL-FO is

446 the solar-thermal separation efficiency (η), which dictates the design of the separator. This

447 efficiency is defined as:[36]

448
$$\eta = \frac{\dot{m}(C_P \Delta T + \Delta H_{mix})}{q_{solar} A} = \eta_1 \times \eta_2 \tag{2}$$

449 where $\dot{m}$ is the mass flow rate, C_P is the specific heat capacity of the diluted draw (approximated

450 as water), ΔT is the difference between the initial and final temperatures of the mixture; ΔH_{mix} is

451 negligible compared to $C_p \Delta T$, A is photonic heater area, and q_{solar} is the incident solar flux.

452 There are two parts to this efficiency: η_1 represents the photo-thermal conversion efficiency of

453 the heater (*i.e.,* the efficiency of capturing sunlight and converting it into IR), and η_2 represents the

454 radiative coupling between the heater and the underlying liquid, as well as the absorption

455 efficiency of the IL-water mixture (*i.e.,* the efficiency of utilizing the captured energy for phase

456 separation). These efficiencies guide the design of the two sub-components of the separator.

457 Maximizing η_1 necessitates the use of a selective solar absorber with a high solar absorptance and

458 low thermal emittance that converts incoming sunlight into heat, as well as an emitter with a high

459 infrared emittance that radiates to the underlying liquid. The spectral properties of the selective

460 solar absorber and the blackbody emitter demonstrated in this work satisfy these criteria to yield a

461 photonic heater efficiency of $\eta_1 \sim 91\%$ owing to optical losses by reflection and thermal emission

462 from the selective absorber surface (fig. S15). Maximizing η_2 requires strong radiative coupling

463 between the emitter and liquid, which is achieved with a radiation view factor close to unity and

464 minimal thermal losses (*e.g.* convection from the heater and liquid surfaces and conduction to the

465 walls of the vessel). Maximizing η_2 also requires emission from the heater to be matched with

466 spectral properties of the IL-water mixture. A view factor ~0.8 was achieved in this work by

467 placing the heater close to the surface of the liquid, and spectral property matching was made

468 possible by blackbody emission at 80 °C (temperature attained by the photonic heater in lab

469 experiments) with a peak wavelength ~8 μm that overlaps with measured absorption profile of the

470 liquid (fig. S16). As thermal losses cannot be measured experimentally, a 2D multi-physics model

471 was developed to estimate losses and determine η_2 (Supplementary Note 8 and table S10). This

472   model reveals that convection losses from the top surface of the heater and absorption of emitted

473   heat by the liquid result in $\eta_2 \sim 55\%$. As a result, the overall solar-thermal separation efficiency is

474   50%, which can be optimized further with design modifications. For example, higher heater

475   temperatures can be attained by reducing convection losses from its surface (*e.g.* using insulation,

476   multi-layer convection shields, vacuum), which consequently increases the radiative power

477   incident on the IL-water mixture. The dimensions of the separator, *i.e.,* its thickness can also be

478   modified to match the thermal penetration depth of incoming infrared radiation, which enables

479   temperatures well-above LCST in under an hour (fig. S23). With these design improvements, a

480   separator efficiency (solar-thermal) of 69% can be obtained due to direct volumetric absorption of

481   radiation by the liquid, which is comparable and even higher than conventional solar collectors

482   operating under similar conditions,[41-42] while also having the added advantage of using noncontact

483   heat transfer. In comparison, heating IL-water mixtures directly with solar energy (*i.e.,* without the

484   photonic heater) would result in an efficiency under 20% due to their poor absorption of sunlight.
