### Abstract

We find strong empirical evidence that the liquidity yield on government bonds in combination with standard economic fundamentals can well account for nominal exchange rate movements. We find impressive evidence that changes in the liquidity yield are significant in explaining exchange rate changes for all the G10 countries, and we stress that the U.S. dollar is not special in this relationship. We show how these relationships arise out of a canonical two-country New Keynesian model with liquidity returns. Additionally, we find a role for sovereign default risk and currency swap market frictions.

### **1. Introduction**

In October 2008 during the 2008 Global Financial Crisis and again in March 2020 at the onset of Covid-19 crisis, the U.S. Federal Reserve cut interest rates more quickly and sharply than central banks of most other major economies, but the U.S. dollar appreciated. According to the standard interest parity condition, low interest rates should depreciate the currency. During both of these periods, analysts refer to a "dash for cash", highlighting the role of demand for liquid assets in influencing exchange rates.<sup>1</sup>

We examine empirically the role of the liquidity return on government bonds in driving exchange rates. Theoretically, Engel (2016) suggests that this return – the non-monetary return that government short-term bonds provide because of their safety, the ease with which they can be sold, and their value as collateral, which is sometimes referred to as the "convenience yield" – may be important in understanding exchange rate puzzles.<sup>2</sup> The intuition for why the government bond convenience yield influences the exchange rate is straightforward. The liquidity that these bonds provide is attractive to investors and influences their investment decisions as if the bonds were paying an unobserved convenience dividend. An increase in the liquidity yield, as measured by the difference between the riskless private bond return and government bond return, will ceteris paribus lead to a currency appreciation much in a similar way that an increase in the interest rate would affect the currency value.

We find for each of the so-called G10 currencies that the relative liquidity yield (the home country yields relative to foreign country yields) has significant explanatory power for exchange rate movements.<sup>3</sup> That is, the role of the liquidity yield in driving exchange rates is not limited to the U.S. but is evident across all the major currencies. Moreover, using guidance from a standard New Keynesian model augmented with a role for liquidity returns on government bonds, we find that the customary determinants of exchange rate movements are statistically and quantitatively important after controlling for the liquidity yields: interest rate differentials and a lagged adjustment term for the real exchange rate (as in Eichenbaum, et al. (2021)) also drive exchange rate movements.

<sup>&</sup>lt;sup>1</sup> See Bianchi, Bigio, and Engel (2021) for a day-by-day analysis of the March, 2020 event.

<sup>&</sup>lt;sup>2</sup> Krishnamurthy and Vissing-Jorgensen (2012) and Nagel (2016) study the convenience yield on U.S. Treasury assets. del Negro et al. (2019) find that convenience yields account for the long-run drop in global real interest rates.

<sup>&</sup>lt;sup>3</sup> Namely, Australian Dollar (AUD), Canadian Dollar (CAD), Euro (EUR), Japanese Yen (JPY), New Zealand Dollar (NZD), Norwegian Krone (NOK), Swedish Krona (SEK), Swiss Franc (CHF), British Pound (GBP) and United States Dollar (USD).

Our study uses measures of the liquidity yield on government bonds, as constructed by Du, et al. (2018a). These measures take the difference between a riskless market rate and the government bond rate to quantify the implicit liquidity yield on the government bond. While Du et al. (2018a) examine the convenience yield of U.S. dollar government securities, an important point of emphasis for us is that the relationship between this liquidity yield and the exchange rate is not exclusively, or even especially, a dollar phenomenon or a crisis phenomenon. Much of the exchange rate literature in recent years has focused on the special role of the dollar, especially at times of heightened global risk, but the role of the liquidity yield goes beyond that.<sup>4</sup> In fact, when we eliminate the U.S. dollar from our empirical work entirely, the importance of the convenience yield is not diminished. Relatedly, we find, using extensive sub-sample analysis, that the role of the liquidity premium is not a phenomenon driven by financial crises. We find that the relationship is particularly strong for the post-2008 sample.

We subject our results to many robustness tests. We refine our liquidity measures with adjustment for covered interest parity (CIP) deviation and default risk suggested by Du et al. (2018a) and construct country-specific liquidity yields rather than relative liquidity yields and find the models perform consistently well. We also find the same pattern for emerging market currencies but weaker quantitatively. In an exercise in the spirit of Meese and Rogoff (1983), we find our empirical model has a significantly better out-of-sample fit than a random walk model.

The liquidity return or convenience yield may arise from the usefulness of some government securities either as collateral for very short-term loans, or from the ease with which they can be sold for cash. Nickolas (2018) defines liquid assets as: "cash on hand or an asset that can be readily converted to cash. An asset that can readily be converted into cash is similar to cash itself because the asset can be sold with little impact on its value." But there is only a fine

<sup>&</sup>lt;sup>4</sup> A partial list of these studies include the contributions of Bruno and Shin (2015, 2017, 2019), Avdjiev et al. (2019 a,b) who emphasize the two-way feedback between the dollar and the financial system. Maggiori (2017) links the reserve currency role of the dollar and exchange rates. Lustig, et al. (2011, 2014), Verdelhan (2018), Hassan and Mano (2019), Avramov and Xu (2019), and Sarno et al. (2012) point to a "dollar factor" in asset returns and returns from a dollar carry trade strategy. Related studies such as Kekre and Lenel (2020), Gourinchas et al. (2020), and Greenwood et al. (2020) build economic models of risk premiums and the U.S. dollar. Gabaix and Maggiori (2015), Adrian et al. (2018), Itskhoki and Mukhin (2021), Adrian and Xie (2020) and Bianchi et al. (2021) relate exchange rates to the global financial system's demand for dollar assets. Caballero et al. (2017, 2020), Gourinchas et al. (2017), Lilley et al. (2019), Jiang et al. (2018, 2020, 2021) relate the exchange rate to demand for safe dollar assets. Rey (2016) and Miranda-Agripinno and Rey (2020) relate U.S. monetary policy, exchange rates and the global financial cycle. Mukhin (2018), Gopinath et al. (2019), Gopinath and Stein (2021) link "dollar currency pricing" to exchange rate behavior. Lustig and Richmond (2020), Richmond (2019), and Jiang and Richmond (2020) examine gravity models of exchange rate risk premiums in which the dollar plays an outsized role.

distinction between liquidity so defined and "safety" as defined by Gorton (2017): "A safe asset is an asset that is (almost always) valued at face value without expensive and prolonged analysis. By design, there is no benefit to producing (private) information about its value, and this is common knowledge." From these definitions, it is clear that safe assets will be liquid, and liquid assets are safe. The role of safe assets in the global economy has been studies extensively in recent literature. In Caballero et al. (2008), Mendoza et al. (2009), Gourinchas and Rey (2011), Maggiori (2017), and Farhi and Maggiori (2018), safe assets play a key role in accounting for global imbalances. Caballero et al. (2015, 2017) explore the role of a shortage of safe assets and their role in the global financial crisis. Gourinchas and Jeanne (2012) explore the consequences of a shortage of safe assets for the stability of the global financial system.

Engel (2016) proposes a model of liquidity return that can reconcile puzzling empirical evidence on failures of uncovered interest parity. Engel et al (2019) and Valchev (2020) document empirical findings that can be explained by a U.S. Treasury liquidity yield. <sup>5</sup> Bianchi et al (2021) propose an endogenous liquidity yield model from a general equilibrium banking setup with deposit shocks. We contribute to the literature by explicitly measuring the liquidity yield and draw direct linkage to exchange rate determination. <sup>6</sup> Engel (2020) uses the same liquidity yield measures to account for the size of "exorbitant privilege" for the U.S. using a VAR estimation.

Our study is closely related to Jiang, et al. (2018, 2021), but with the following differences: First, our empirical specification is derived from a simple theoretical general equilibrium model, which is important in understanding the endogenous relationship of liquidity yield, interest rate, inflation, and exchange rate.<sup>7</sup> It also pins down the permanent component of non-stationary nominal exchange rates. The model augments the "canonical" three-equation open economy New Keynesian model with a model of the liquidity yield, which emphasizes that the liquidity yield is a "missing link" that helps solve exchange rate puzzles. Second, consistent with the model, our empirical work finds strong evidence for the role of government liquidity yields, interest rates and

<sup>&</sup>lt;sup>5</sup> Linnemann and Schabert (2015) also posit a relationship between liquidity returns and exchange rate behavior. Their paper does not provide an empirical test of the relationship between the liquidity return and exchange rates. Their model postulates a negative relationship between the liquidity yield and interest rates, contrary to the model of Nagel (2016), Engel (2016), and this paper, and contrary to the evidence in Nagel (2016) and this paper.

<sup>&</sup>lt;sup>6</sup> A bit of our preliminary findings were first reported at a conference at the Bank for International Settlements on "International macro, price determination and policy cooperation" in September, 2017. The publicly available slides for that lecture can be found at <u>https://www.bis.org/events/confresearchnetwork1709/programme.htm</u>

<sup>&</sup>lt;sup>7</sup> For example, we note that in our equilibrium model, the liquidity return and the interest rate play somewhat different roles arising from the role of government bond returns and liquidity yield in the monetary policy rule. Thus, interest rates respond endogenously to inflation in a way that the convenience yield does not.

adjustment toward purchasing power parity in monthly data for all G10 currencies, while Jiang, et al. look only at quarterly changes in the U.S. dollar. That is, we emphasize that the liquidity yield is not solely a U.S. dollar story. We also extend the results to emerging market currencies. Finally, using the decomposition of Du, et al. (2018a), we find additional explanatory power arising from default risk and forward market frictions in a way that is compatible with our model. This latter is important because the premium on government bonds is influenced not only by the liquidity yield, or "convenience yield", of government bonds, but also by default risk and frictions in forward markets for foreign exchange.<sup>8</sup> Jiang et al. (2021) further explores the relationship between the LIBOR basis – the deviation from covered interest parity for LIBOR rates – and the U.S. dollar exchange rate. That study also examines the relationship between monetary policy shocks and the convenience yield, investigates the term structure of the convenience yield, and estimates a VAR in order to estimate a variance decomposition that measures the contribution of the convenience yield to exchange rate movements. It also tests the predictability of excess returns using the relative convenience yield.

The exchange rate determination literature has pointed to market imperfections of various stripes – arising for example from balance-sheet constraints, incomplete risk sharing, default risk, noise traders – as potentially playing an important role in exchange rate determination. These studies shed light on what has come to be known at the "exchange-rate disconnect" puzzle, as coined by Obstfeld and Rogoff (2000).<sup>9</sup> Many of these explanations can be collapsed into deviation from uncovered interest parity, which is now introduced as a standard feature in open-economy New Keynesian models to reproduce to some extent the observed volatility of real exchange rates.<sup>10</sup> Indeed, Itskhoki and Mukhin (2021) show that this deviation is key to being able to account for the disconnect puzzle. These models inevitably treat the deviation as an unobserved variable. One interpretation of our model and findings is that the uncovered interest parity deviation is partly observable and can be well-measured by the relative liquidity yield on government bonds.

<sup>&</sup>lt;sup>8</sup> Avdjiev, et al. (2019b) document the role of deviations from covered interest parity for the value of the U.S. dollar. <sup>9</sup> Engel (2014) provides a recent survey. Itskhoki and Mukhin (2021) is a recent attempt to build a model to account for the disconnect. One notable determinant of nominal exchange rate movements is the lagged real exchange rate, which arises from adjustment to real exchange rate disequilibrium. This point was made clearly by Mark (1995), and has found strong recent support by Eichenbaum, et al. (2021).

<sup>&</sup>lt;sup>10</sup> See Kollmann (2002) for an early example.

Liquidity and its role in exchange-rate determination has been explored from a variety of angles. Grilli and Roubini (1992) and Engel (1992) are earlier, related works. Brunnermeier et al. (2009), Adrian et al. (2018) and Bruno and Shin (2015) consider a liquidity effect on exchange rates arising from banks' balance sheets. One can identify the notions of liquidity in these studies with "funding" liquidity, as defined in Brunnermeier and Petersen (2009), but other work has looked at the role of "market" liquidity. A prominent recent study is Gabaix and Maggiori (2015) that considers financial constraints that prevent full liquidity to arbitrage international money markets. A related study is Pavlova and Rigobon (2008) which investigates the role of portfolio constraints. Melvin and Taylor (2009), Banti et al. (2012), and Mancini et al. (2013) empirically study of the role of liquidity in foreign exchange markets.

There is a long history of attributing a role to the "safe haven" effect on currency values. Fatum and Yamamoto (2016), look at this phenomenon during the global financial crisis, defining a safe currency as "a currency that increases its relative value against other currencies as market uncertainty increases." The idea of a safe haven effect is an old one – see, for example, Dooley and Isard (1985), Isard and Stekler (1985) or Dornbusch (1986). Here we might argue that during times of global uncertainty, certain assets such as short-term government securities become more valued for their liquidity. There can be other channels through which the safe haven phenomenon works. Farhi and Gabaix (2015) model safe haven currencies as ones that appreciate during times of global downturns, a concept that has been tested empirically by Ranaldo and Söderlind (2010). Obstfeld and Rogoff (2002) speak of risk more generally, which could encompass both the liquidity channel and the hedging channel.

Section 2, which guides our empirical work, presents an equilibrium New Keynesian model in which government bonds pay a liquidity return. Section 3 presents the results of our empirical investigation. Section 4 concludes.

#### 2. A Model of Liquidity and Exchange Rates

Our model is an analytical version of an off-the-shelf New Keynesian open economy model, but with the addition of the liquidity yield. When augmented with these convenience yields, the model provides guidance for the empirical specification under a general equilibrium framework.

Following Krishnamurthy and Vissing-Jorgensen (2012), Engel (2016), Nagel (2016), and Jiang, et al. (2018, 2021), we posit that the ex-ante excess return on short-term government bonds in one country relative to another is attributable to an unobserved liquidity payoff. Let  $i_t$  be the one-period interest rate in the "home" country government bonds (we present the model in the context of two countries, "home" and "foreign".)  $i_t^m$  is the return on a short-term, one-period market instrument. The liquidity premium is the difference in these two rates:  $\gamma_t = i_t^m - i_t$ . Assume that the market rate is collateralized and the government rate adjusts for the cost of credit default swaps, so these rates represent the default-risk-free returns. The empirical section will adjust the returns for default risk using credit default swap (CDS) data.

Under this formulation, we should observe  $\gamma_t > 0$  if the government bond is more liquid. Investors are willing to hold the government bond instead of the market instrument because the government bond is more easily sold on markets or is more readily accepted as collateral. It may be that some agents in the economy have no need for liquidity, in which case their holdings of the government bonds are zero. In particular, foreign agents may hold no home government bonds because they do not value the liquidity of those assets. But private agents cannot short government bonds – that is, private agents (in either economy) cannot borrow at the rate  $i_t$ , because the assets they issue do not have the same liquidity as government bonds.

Analogously, in the foreign country, there is a liquidity yield given by  $\gamma_t^* = i_t^{*m} - i_t^*$ , where the \* superscript denotes the foreign-country equivalents of the home-country variables.

We assume there is a deviation from uncovered interest parity for the market instruments,  $r_t$ , that is stochastic, exogenous and uncorrelated with the other shocks (monetary and liquidity) in the model. We remain agnostic about the source of this deviation.  $r_t$  could be a deviation from rational expectations, some sort of market friction, or perhaps a foreign exchange risk premium. In Jeanne and Rose (2002), Devereux and Engel (2002), and Itskhoki and Mukhin (2021), this term arises because of the presence of noise traders. We assume that  $r_t$  is uncorrelated with other shocks introduced into the model, to the monetary policy rule and to the liquidity return:

(1) 
$$i_t^{*m} + E_t s_{t+1} - s_t - i_t^m = r_t$$
,

where  $s_t$  is the log of the exchange rate (expressed as the home currency price of the foreign currency.)<sup>11</sup>

Let  $\eta_t$  be the liquidity return on home relative to foreign government bonds:

(2) 
$$\eta_t = \gamma_t - \gamma_t^* = (i_t^m - i_t) - (i_t^{m^*} - i_t^*) = (i_t^m - i_t^{m^*}) - (i_t - i_t^*).$$

Then we can rewrite (1) as:

(3) 
$$i_t^* + E_t s_{t+1} - s_t - i_t = \eta_t + r_t.$$

The expected excess return on foreign one-period government bonds (relative to home bonds) is determined in part by the liquidity yield of home government bonds relative to foreign bonds. When home bonds are more liquid, the foreign bonds must pay a higher expected monetary return.

Now, iterate equation (3) forward, as in Campbell and Clarida (1987) and others:<sup>12</sup>

(4) 
$$s_{t} = -E_{t} \sum_{j=0}^{\infty} \left( i_{t+j} - i_{t+j}^{*} - \left( \overline{i - i^{*}} \right) \right) - E_{t} \sum_{j=0}^{\infty} \left( \eta_{t+j} - \overline{\eta} \right) - E_{t} \sum_{j=0}^{\infty} \left( r_{t+j} - \overline{r} \right) + \lim_{k \to \infty} \left( E_{t} s_{t+k} - k \left( \overline{s_{t+1} - s} \right) \right).$$

We assume that the interest differential,  $i_t - i_t^*$ ; the liquidity return,  $\eta_t$ , and the u.i.p. deviation,  $r_t$ , are all stationary random variables, but  $s_t$  follows a unit root process.<sup>13</sup> An overbar represents unconditional means:  $\overline{i - i^*}$ ,  $\overline{\eta}$ ,  $\overline{r}$ . Here,  $\lim_{k \to \infty} \left( E_t s_{t+k} - k(\overline{s_{t+1}} - s) \right)$ , which is a random variable when the exchange rate has a unit root, is the permanent component of the nominal exchange rate - in the sense that Beveridge and Nelson (1981) use that term in their permanent-transitory

<sup>&</sup>lt;sup>11</sup> A simplification implicit here is that the standard "Fama" regression would not reject the null hypothesis. Under our specification for monetary policy, introduced below, with inflation predetermined and monetary shocks that are independent of the shocks to  $r_i$ , we should not be able to reject uncovered interest parity using our measures of returns on market instruments. Online Appendix A1. shows, however that during our time sample, the null hypothesis is not rejected in the Fama regression for any of the G10 currencies.

<sup>&</sup>lt;sup>12</sup> Engel (2016) and Jiang, et al. (2021) relate the expected excess returns to the liquidity yield.

<sup>&</sup>lt;sup>13</sup> Technically, we assume  $i_t - i_t^*$ ,  $\eta_t$ , and  $r_t$  are square summable, which insures that the infinite sums converge. Any finite order ARMA process, for example, is square summable.

decomposition. The term  $s_{+1} - s$  represents the trend in the log of the nominal exchange rate.

There is consensus that nominal exchange rates among high-income countries contain unit roots. For example, if monetary policy is set by a rule for money supplies, any permanent change in the money supply would lead to a permanent change in the nominal exchange rate. If monetary policy is set by an interest-rate rule such as a Taylor rule, the exchange rate will contain a unit root unless the interest rate rule targets the nominal exchange rate.<sup>14</sup>

Equation (4) already points to the intuition of our empirical specification. It says that when the infinite sum of the expected current and future home interest rates rises relative to the expected infinite sum of current and future foreign interest rate, the home currency appreciates ( $s_t$  falls.) That is a well-known channel of influence, which is at work in, for example, the famous Dornbusch (1976) model. A higher relative liquidity return on home government bonds also leads to an appreciation of the domestic currency. In this equation, the liquidity return and the interest rate are just two components of the return on government bonds, and so their impact on the exchange rate is identical. In the model below, the interest rates and liquidity return play different roles in the monetary policy rule and are endogenously determined.

Equation (4) is not a full model of nominal exchange rate determination. Comparative statics exercises that change the interest rate differential or the components of expected excess returns holding the permanent component of the exchange rate constant can be misleading. A full macro model is necessary to understand how the components on the right-hand-side of equation (4) relate to the exchange rate in equilibrium. For example, not all nominal interest rate changes are the same. In a traditional monetarist model of exchange rates, a permanent one-time increase in the monetary growth rate in the home country would immediately raise inflation, and therefore raise the inflation premium incorporated in the nominal interest rate.  $i_{t+j} - i_{t+j}^*$  would increase for all time periods, but that also implies an increase in the unconditional mean of the relative interest rates,  $\overline{i-i}^*$ . In that case, there would be no change in the first term on the right hand side of equation (4):  $E_t \sum_{j=0}^{\infty} (i_{t+j} - i_{t+j}^* - (\overline{i-i}^*))$  would be unaffected. However, this change would lead to an increase in the permanent component of the exchange rate. The size of the increase is model-

<sup>&</sup>lt;sup>14</sup> See Benigno and Benigno (2008). See Engel and Wu (2021) for recent evidence on the unit root in nominal exchange rates.

dependent, but a classic result is that an increase in the growth rate of x percent leads to an immediate permanent depreciation of greater than x percent, which the literature referred to as the "magnification effect".<sup>15</sup> The conclusion is that equation (4) by itself, which represents the international financial market equilibrium condition, is not sufficient to determine the exchange rate. In order to determine the exchange rate, we need a model of the determination of interest rates, and of the permanent component of the nominal exchange rate. One cannot infer the effects of the liquidity yield or interest rates on exchange rates by changing one of the components of (4) holding the others constant, because in a dynamic general equilibrium, the components interact.<sup>16</sup>

We adapt the model from Engel (2016), based in turn on Nagel (2016), in which the liquidity return on the home bond is positively related to the interest rate:

(5) 
$$\eta_t = \alpha \left( i_t - i_t^* \right) + v_t, \quad \alpha > 0.$$

Appendix A1 derives this equation, extending the analysis of Engel (2016). The positive relationship between the relative liquidity return and the interest differential arises as in Nagel (2016). When the monetary authority tightens monetary policy by reducing the supply of money and raising interest rates, liquid assets that can substitute for money become more valued for their liquidity services and so pay a higher liquidity return.<sup>17</sup>

The remainder of the model adopts a New Keynesian framework. We assume that prices in each country are sticky in nominal terms and set one period in advance. We posit that there is local-currency pricing, so that each firm, in both countries, sets two prices – one in home currency for sale in the home country, and one in foreign currency for sale in the foreign currency. Online Appendix B1 derives the home relative to foreign Phillips curve,

(6) 
$$\pi_t - \pi_t^{\hat{}} = \theta q_{t-1} + E_{t-1} s_t - s_{t-1}.$$

<sup>17</sup> This equation does not necessarily imply a positive relationship between the relative liquidity yields and the relative interest rates in equilibrium. We introduce below a monetary policy rule in which these two variables are negatively related. An increase in  $v_t$  here leads to an increase in  $\eta_t$ , which in turn will lead monetary policy makers to reduce  $i_t - i_t^*$ , leading to a negative correlation between  $i_t - i_t^*$  and  $v_t$ .

<sup>&</sup>lt;sup>15</sup> See, for example, Frenkel (1976).

<sup>&</sup>lt;sup>16</sup> Here we differ from Jiang, et al. (2021), who take nominal interest rates as exogenous and assume the nominal exchange rate is stationary.

In this equation,  $q_{t-1}$  is the log of the real exchange rate (the price of the consumer basket in the foreign country relative to the home country),  $\pi_t$  is home consumer price inflation between t-1 and t, and  $\pi_t^*$  is foreign consumer price inflation. Note that because prices are set one period in advance, the inflation rates,  $\pi_t$  and  $\pi_t^*$ , are observable at time t-1. Under this specification of price adjustment, the real exchange rate is a stationary random variable and long-run purchasing power parity holds. The pricing to market disequilibria are expected to dissipate over time.

Small modifications to the standard open-economy Phillips curve are introduced here to motivate our empirical model of the exchange rate in an intuitive way. As is well-known from Benigno (2004), price stickiness would not matter at all for the adjustment of the real exchange rate with a standard Calvo-pricing equation, unless interest-rate smoothing is introduced into the monetary policy rule. Engel (2019) shows how the Phillips curve here, along with serially correlated errors in the monetary policy rule produces very similar real exchange rate behavior as the Calvo pricing model with interest rate smoothing, but this model is more analytically convenient.

The final component of the model is the characterization of monetary policy behavior. We assume that the monetary authority has control of a policy rate that is a weighted average of the government bond rate and the market rate, which it uses to target inflation. In the home country:

(7) 
$$(1-\psi)i_t + \psi i_t^m = \sigma \pi_t + u_t, \quad 0 \le \psi \le 1$$

In practice, the policy rate is closely aligned with the government bond rate in the countries in this study.<sup>18</sup> We use this specification to avoid introducing yet another interest rate, the monetary policy rate, and remain agnostic on the correct value of  $\psi$ . None of the qualitative conclusions from the model depend on the value of  $\psi$ . Another interpretation of this equation is that the government interest rate is the policy rate, and the policy maker targets the liquidity premium by lowering the policy rate when the market places a high value on liquidity:

$$i_t = \sigma \pi_t - \psi \left( i_t^m - i_t \right) + u_t$$

<sup>&</sup>lt;sup>18</sup> Online Appendix A2 provides evidence to support this statement.

The stability condition in this model is given by  $\sigma > \frac{1+\alpha}{1+\alpha\psi}$ , and we assume  $\sigma > 1$ .  $u_t$  is a deviation from the monetary policy rule. There is an analogous equation in the foreign country. Subtracting the foreign Taylor rule from the home Taylor rule gives us:

(8) 
$$i_t - i_t^* = \sigma(\pi_t - \pi_t^*) - \psi \eta_t + u_t - u_t^*.$$

The relative error terms in the monetary rules follow a first-order autoregressive process:

(9) 
$$u_t - u_t^* = \delta \left( u_{t-1} - u_{t-1}^* \right) + \xi_t, \quad 0 \le \delta < 1$$

where  $\mathcal{E}_t$  is a mean-zero, i.i.d. random variable.

The exogenous variables are monetary shocks (in equation (8)), the uncovered interest parity shocks in equation (1), and liquidity shocks in equation (5). We have already noted that monetary shocks are assumed to be follow an AR(1) process. We assume that there is persistence in liquidity, and that  $v_t$  also follows a first-order autoregressive process:

(10) 
$$v_t = \rho v_{t-1} + \varepsilon_t,$$

where  $\varepsilon_t$  is mean-zero, i.i.d., and  $0 \le \rho < 1$ . Furthermore, we assume that the deviation from uncovered interest parity for market interest rates also follows an autoregressive process given by:

(11) 
$$r_t = \zeta r_{t-1} + \omega_t, \quad 0 \le \zeta < 1.$$

Equations (3), (5), (6) and (8) – the international financial market equilibrium condition, the model of the liquidity premium, the (relative home to foreign) open economy Phillips curve, and the (home relative to foreign) monetary policy rule – give us a complete dynamic system for the real exchange rate, inflation and interest rates. The model incorporates slow adjustment of the real exchange rate because of nominal price stickiness, governed by the parameter  $\theta$ , the fraction of the firms that reset their price optimally each period. As Eichenbaum, et al. (2021) have recently emphasized, empirically almost all the adjustment of real exchange rate comes through adjustment by the nominal exchange rate. Eichenbaum, et al. (2021) demonstrate that this empirical regularity can be captured in a New Keynesian model with strong inflation targeting (large value of  $\sigma$ ) which leads to a low inflation variance even if the variance of the real exchange rate is large. That regularity indeed does not depend on sluggish price adjustment, but would be true even under flexible goods prices when monetary policy stabilizes the nominal price level.

The model can be solved by hand.<sup>19</sup> For the real exchange rate, we find:

(12)

$$q_{t} = -\left(\frac{\sigma(1+\alpha) - (1-\theta)(1+\alpha\psi)}{\theta(1+\alpha\psi)}\right) \left(\pi_{t} - \pi_{t}^{*}\right) - \left(\frac{(1+\alpha)\left[\sigma(1+\alpha) - (1-\theta)(1+\alpha\psi)\right]}{\theta(1+\alpha\psi)\left(\sigma(1+\alpha) - \delta(1+\alpha\psi)\right)}\right) \left(u_{t} - u_{t}^{*}\right) - \left(\frac{(1-\psi)\left[\sigma(1+\alpha) - (1-\theta)(1+\alpha\psi)\right]}{\theta(1+\alpha\psi)\left[\sigma(1+\alpha) - \rho(1+\alpha\psi)\right]}\right) v_{t} - \left(\frac{\sigma(1+\alpha) - (1-\theta)(1+\alpha\psi)}{\theta\left[\sigma(1+\alpha) - \zeta(1+\alpha\psi)\right]}\right) r_{t}$$

The inflation variables at time *t* are predetermined, so (12) expresses the real exchange rate in terms of predetermined and exogenous variables. A relative monetary tightening in the home country (an increase in  $u_t - u_t^*$ ) causes a real appreciation of the home currency. Similarly, an increase in the liquidity yield on home government bonds leads to a real appreciation. Note that as inflation targeting becomes more stringent, so  $\sigma$  is larger, the real exchange rate reacts more to monetary policy shocks if  $\delta < 1 - \theta$ . If  $\rho < 1 - \theta$ , a larger  $\sigma$  increases the response of the real exchange rate to changes in the relative liquidity return. We assume in all following discussion that both preceding inequalities are satisfied. Also, the greater price stickiness (smaller  $\theta$ ), the larger the response of the real exchange rate to monetary policy shocks and the relative liquidity returns.

Referring to equation (4), the expected values of future interest rates depend on all of the shocks to the model, as do the expected values of future convenience yields. In this model, the expected future interest rates, liquidity yield and risk premiums are all endogenous functions of the state variables on the right hand side of equation (12). The real exchange rate can be solved in terms of these time t variables because shocks have only first-order serial correlation. The final term in (4), the permanent component of the nominal exchange rate, is endogenously determined

<sup>&</sup>lt;sup>19</sup> The full derivation of the model is in Online Appendix B2.

by the convergence of prices and the exchange rate toward the unconditional mean of the real exchange rate.

Our empirical analysis aims at explaining movements in the log of the nominal exchange rate,  $s_t - s_{t-1}$  in terms of observable variables. We derive:

(13) 
$$s_{t} - s_{t-1} = \beta_{1}q_{t-1} + \beta_{2}(\eta_{t} - \eta_{t-1}) + \beta_{3}(i_{t} - i_{t}^{*} - (i_{t-1} - i_{t-1}^{*})) + \beta_{4}\eta_{t-1} + \beta_{5}(i_{t-1} - i_{t-1}^{*}) + z_{j,t}$$

where

$$\begin{split} \beta_{1} &= -\left(\frac{\sigma(1+\alpha)(1-\theta-\delta)}{\sigma(1+\alpha)-\delta(1+\alpha\psi)}\right) < 0 \\ \beta_{2} &= -\left(\frac{\left[\sigma(1+\alpha)-(1-\theta)(1+\alpha\psi)\right]\left[\sigma(1+\alpha)-(\delta(1-\psi)+\rho\psi(1+\alpha))\right]}{\theta(\sigma(1+\alpha)-\delta(1+\alpha\psi))(\sigma(1+\alpha)-\rho(1+\alpha\psi))}\right) < 0 \\ \beta_{3} &= -\left(\frac{\left[\sigma(1+\alpha)-(1-\theta)(1+\alpha\psi)\right]\left[(1+\alpha)(\sigma-\rho)+\alpha\delta(1-\psi)\right]}{\theta(\sigma(1+\alpha)-\delta(1+\alpha\psi))(\sigma(1+\alpha)-\rho(1+\alpha\psi))}\right) < 0 \,. \end{split}$$

and  $z_t = -\left(\frac{\sigma(1+\alpha)+\theta-1}{\theta(\sigma(1+\alpha)-\varsigma)}\right)\omega_t + z_1r_{t-1}$ 

The full expressions for  $\beta_4$ ,  $\beta_5$  and  $z_1$  are presented in Online Appendix B3.

This specification for the depreciation of the exchange rate includes, first, an error correction term as the nominal exchange rate adjusts to disequilibrium in the real exchange rate. Second, the change in the interest differential affects the exchange rate as in standard New Keynesian models. Third, the change in the relative liquidity return on government bonds plays a role in influencing the exchange rate. Lagged levels of the relative interest differentials and liquidity returns capture the dynamic adjustment. Under the parameter restrictions of the model –  $\sigma > 1$ ,  $\alpha > 0$ ,  $0 \le \theta < 1$ ,  $0 \le \rho < 1$ , and  $\rho < 1-\theta$  – ceteris paribus, an increase in  $q_{t-1}$ , and increase in  $i_t - i_t^* - (i_{t-1} - i_{t-1}^*)$ , and an increase in  $\eta_t - \eta_{t-1}$  all lead to a decline in  $s_t - s_{t-1}$ . That is, the home currency appreciates to correct for a real undervaluation, and it appreciates in response to a relative increase in either the home interest rate or the home liquidity return. The error term,  $z_t$ , is a function of the dynamics of the deviation from uncovered interest parity, which is assumed

not to be observable by the econometrician. It is by construction uncorrelated with the explanatory variables in the regression. The derivation implies that there may be serial correlation in the regression error. However, as shown in Online Appendix B5, for parameters calibrated to the data, the serial correlation of the residual is very low (around 0.02, for example), as it is in the data.<sup>20</sup>

The estimating equation (13) isolates the effects of an increase in liquidity demand. Controlling for the government interest rate differential,  $i_t - i_t^*$ , as in (13), means that an increase in the liquidity premium,  $\eta_t$ , raises the relative market interest differential,  $i_t^m - i_t^{m^*}$ . Intuitively, if government bonds in the home country become more valuable for their liquidity services, but  $i_t - i_t^*$  does not change, then the market interest rate on home securities must rise, leading to incipient capital inflows and an immediate appreciation of the home currency.

Before turning to the data, we note a few features of our empirical specification based on (13). As in our model, we follow convention and treat nominal exchange rates as non-stationary random variables. Considering much evidence, from Mark (1995) to more recent empirical evidence in Engel (2016) and Eichenbaum, et al. (2021), we choose to treat the real exchange rate as stationary, and the nominal exchange rate adjusts in the direction of restoring purchasing power parity. Relative interest rates and relative liquidity returns are also modeled as stationary. We allow dynamics by including contemporaneous and lagged values of these variables. Because these variables are serially correlated, we enter them in the specification as in (13) with the first difference in the returns and the lagged level of the returns. This reduces the multicollinearity that would be present if these variables were included in contemporaneous and lagged levels and gives us the natural interpretation that changes in relative interest rates and changes in relative liquidity yields influence changes in the log of the nominal exchange rate.

 $\beta_3$  measures the impact of monetary policy shocks,  $u_t - u_t^*$ , on  $s_t$ , while  $\beta_2$  quantifies the effect of shocks to the relative liquidity yield,  $v_t$ , on the log of the exchange rate. To see this, first observe from the relative Taylor rules, (8), that the home relative to foreign interest rate differential depends on relative inflation,  $\eta_t$  and the monetary policy shocks. However, from equations (6) and (3), we see that relative inflation,  $\pi_t - \pi_t^*$  is predetermined and a function of the

<sup>&</sup>lt;sup>20</sup> See Online Appendix B3 for the derivation of equation (13), and of the serial correlation of the residual.

lagged interest rate differential and liquidity yield,  $i_{t-1} - i_{t-1}^*$  and  $\eta_{t-1}$ .<sup>21</sup> Because these latter two variables and  $\eta_t$  are controlled for in (13), the independent effect of  $i_t - i_t^*$  arises only from the monetary policy shocks. Equation (5) finds  $\eta_t$  is a function of the interest rate differential as well as the independent shocks to liquidity. Since the regression equation controls for  $i_t - i_t^*$ , the independent effects of the shocks to liquidity are measured by the coefficient on  $\eta_t$ .

# 3. Empirical Investigation of Government Bond Liquidity and Exchange Rates

In this section, we present our empirical results. We first describe how we construct the measure of government bond liquidity in 3.1. Subsection 3.2 presents our baseline result that the change in the relative government bond liquidity returns is strongly correlated with exchange rate movements. We show our results are robust to controlling for certain market frictions in section 3.3. In subsection 3.4, we further confirm that country-specific government bond liquidity matters. Finally, in subsection 3.5, we conduct an out-of-sample fit exercise a la Meese and Rogoff (1983) and find that our model's prediction significantly outperforms a random walk model.

Throughout the section, we denote the foreign variable as  $X_t^*$  if the context is not country j specific. For example, we use  $i_t^*$  for the foreign interest rate on a government bond. Whenever needed, we denote the variables of a foreign country j as  $X_{j,t}^*$ , for example,  $i_{j,t}^*$  for the interest rate of a government bond for the foreign country j.

#### **3.1.** Construction of Liquidity Measure

The word "liquidity" appears in different economic contexts with different meanings. Here, it refers to a non-observable non-pecuniary return that investors enjoy when holding the asset. We consider two measures of the term  $i_t^m - i_t^{m^*}$  in equation (1). The first uses LIBOR swap rates: (14)  $\hat{\eta}_t = IRS_t - IRS_t^* + i_t^* - i_t$ 

<sup>&</sup>lt;sup>21</sup> Relative inflation would also be a function of lagged r, but we have already argued that because serial correlation is essentially zero in our regressions, the impact of lagged r as a "left out" variable in our regressions is minimal.

where  $IRS_t$  ( $IRS_t^*$ ) refers to the home (foreign) return on LIBOR swaps. The second uses the forward premium:

(15) 
$$\tilde{\eta}_t \equiv f_{t,t+1} - s_t + i_t^* - i_t$$

where  $f_{t,t+1}$  is the log of forward rate and  $s_t$  is the log of the spot exchange rate, both expressed in home currency price of a foreign currency.

There are two ways to interpret  $\eta_t$ . First, as the term  $(i_t^m - i_t) - (i_t^{m^*} - i_t^*)$  suggests, it is a relative measure of difference between marketable securities and government bond yield in the home and foreign country. This interpretation accords well with the  $\hat{\eta}_t$  measure in equation (14), where we are using LIBOR swap rates as the empirical counterpart of our model's market interest rates.

Second, as described by  $f_{t,t+1} - s_t + i_t^* - i_t$ , the first three terms can be understood as the payoff of a synthetic home government bond that is constructed by buying the foreign government bond and eliminating exchange rate risk by entering a forward contract. Since the home government bond and the synthetic home government bond pay equivalent pecuniary returns, the difference between the two gives a measure of the relative difference in liquidity services the home and foreign government bonds provide. Under this interpretation, we are measuring relative liquidity yields by looking at relative government interest rates, correcting for foreign exchange risk. This motivates our baseline measure  $\tilde{\eta}_t$  in equation (15).

We employ the procedure developed by Du, et al. (2018a) to obtain  $\hat{\eta}_t$  and  $\tilde{\eta}_t$  for any pair of home currency *i* and foreign currency *j* (90 pairs in total) for the G-10 currencies. To give a sense of how this liquidity measure behaves, we plot the liquidity measure ( $\tilde{\eta}_t$ ) against the nominal exchange rate of each home currency *i* and foreign currency *j* in Figure 1. For each time period, we take a simple average across foreign currency *j* to improve visual representation. There is already a negative relationship between the mean exchange rate and mean liquidity measure, meaning a higher government bond liquidity relative to the rest of the G10 currency country is associated with a strong currency contemporaneously. Unless otherwise specified, our study uses end-of-month monthly data from January 1999 to January 2018.<sup>22</sup> We use exchange rates and forward rates from Thomson Reuters Datastream. The consumer price indexes and unemployment rates are from the IMF IFS. The government yield data is obtained from Bloomberg, Datastream and central banks. The LIBOR swap rates are from Bloomberg. The credit default swap data is from Bloomberg and IHS Markit. We provide the data source details in Appendix A2 and summary statistics for the variables we used in Appendix A3. Online Appendix A reports a large number of robustness checks. We employ panel fixed effect regressions in all the reported estimates to make use of cross-country time series information but at the same time allow for time-invariant heterogeneity. To account for the possibility of cross-sectional correlated estimation errors, we report standard errors that allow for non-diagonal covariance of the error terms. We estimate the regression using ordinary least squares (OLS). The error terms estimated from the OLS are then used to construct estimates of the variance-covariance matrix of the error term. Consistent statistical inference (for example, significance) can be conducted using this estimated variance-covariance matrix.<sup>23</sup>

#### **3.2 Baseline Results**

To investigate the empirical relationship between government bond liquidity and exchange rates for the G10 countries, we estimate the following panel monthly fixed effect regression from equation (13):<sup>24</sup>

(16) 
$$\Delta s_{j,t} = \alpha_j + \beta_1 q_{j,t-1} + \beta_2 \left( \Delta \eta_{j,t} \right) + \beta_3 \left( \Delta i_{j,t}^R \right) + \beta_4 \eta_{j,t-1} + \beta_5 i_{j,t-1}^R + u_{j,t},$$

where  $s_t$  is the log nominal exchange rate,  $q_t$  is the log real exchange rate,  $\eta_t$  is a measure of liquidity,  $i_t^R = i_t - i_t^*$  is the home minus foreign government bond interest rate differential,  $\Delta X_t = X_t - X_{t-1}$  for any variable *X*.

<sup>&</sup>lt;sup>22</sup> Whenever needed, we linearly interpolate the quarterly variable to monthly variable. For example, we interpolate the Australia and New Zealand CPI to obtain monthly real exchange rates.

<sup>&</sup>lt;sup>23</sup> The standard errors reported in the tables do not correct for time dependence of the residuals. The G10 exchange rates are famously nearly random walks at the monthly frequency. The standard errors are more precisely estimated if this assumption is true. In Online Appendix A15, we report three of our baseline regressions results with Driscoll-Kraay (1998) standard errors, which account for both cross-sectional correlation and autocorrelation. The conclusions on statistical significance are unchanged.

<sup>&</sup>lt;sup>24</sup> We have followed the practice of the empirical exchange rate literature, which might be described as regularization, to avoid overfitting the model with unrestricted coefficients across foreign countries. See Online Appendix B6 for a detailed discussion.

As will become clear, our results - qualitatively, quantitatively, and by statistical significance – are essentially the same for both measures of  $\eta_t$ .<sup>25</sup> We first present the results using the measure of  $\eta_t$  given in equation (14) that uses LIBOR swap rates, but we present many of our detailed results and robustness tests using the measure given in (15) for three reasons. First, Baba and Packer (2009) note that financial institutions that prefer a short position in one currency and long in another find it cheaper to use a foreign currency swap (earning  $f_{t,t+1} - s_t$ ) rather than taking a long deposit in one currency and borrowing in the other (earning  $IRS_t - IRS_t^*$ .) Second, we use definition (15) in order for our results to be most directly related to those in other recent studies. In the case where the U.S. is assumed to be the home country, Du, et al. (2018a) denotes the  $\tilde{\eta}_t$ term here as the U.S. Treasury Premium,  $\Phi_{i,n,t}$ , which is the *n*-year deviation from covered interest parity between government bond yields in the United States and country *j*. Jiang, et al. (2021) take the U.S. as the home country and define  $-\tilde{\eta}_t$  as a cross-country average over nine large markets relative to the dollar. Third, for some currencies, there are longer samples using the measure from (15) rather than from (14). However, the first two sets of results we report demonstrate that the conclusions do not depend on the measure, either qualitatively, or to a large extent, quantitatively.

Table 1A reports the regression coefficient estimates of (16), using  $\hat{\eta}_t$  from equation (14) as the measure of  $\eta_t$ .<sup>26</sup> Each row of the table represents the estimation results that take the country of the currency in the first column as the home country and rest of the nine countries as the foreign countries. When constructing the variables, we use one-year swap rates and one-year government yields.<sup>27</sup> The real exchange rates are constructed using consumer price levels.

First, consistent with our theoretical prediction and the empirical results of Eichenbaum, et al (2021), the coefficient estimates for  $q_{j,t-1}$  are all negatively significant, implying that real

<sup>&</sup>lt;sup>25</sup> The difference between the two measures,  $\tau_t = f_{t,t+1} - s_t + IRS_t^* - IRS_t$ , is a measure of deviations from covered interest rate parity for interest rate swaps. In section 3.3, we explore the relationship between the covered interest parity deviation *per se* and exchange-rate changes.

<sup>&</sup>lt;sup>26</sup> To keep the table visibly clear, we only report the main coefficient estimates of interest and refer readers to Online Appendix A5 for the full regression tables.

 $<sup>^{27}</sup>$  See the discussion and robustness tests below for the choice of one-year tenor. Online Appendix A2 shows that for our countries, the average correlation rate between the policy rate and the one-year bond rate that we use is 0.967.

exchange rates adjust through nominal exchange rates. The average coefficient estimate is approximately -0.023, implying a 2.3% adjustment of the nominal exchange rate in the direction of the long-run real exchange rate, per month. It is interesting to note that the estimated adjustment of the dollar exchange rate is around half the size of the average (across currencies) adjustment coefficient, suggesting a more persistent real exchange rate.

Second, we find that a positive change in the relative interest rate (home minus foreign) drives a contemporaneous home currency appreciation, which matches the traditional interest rate and exchange rate relationship. While almost all monetary, sticky-price models of exchange rates predict such a relationship, empirical support for even a contemporaneous relationship between interest rates and exchange rates has not been universally strong in previous studies.<sup>28</sup> It may be that the importance of the interest rate channel requires controlling for the error-correction term and liquidity yields, as in our specification. We find the interest rate effect is strongly statistically significant for all ten currencies. The average coefficients, across the currencies, is -5.10, which means that a 100 basis point increase in the annualized interest rate in the home currency relative to the foreign country leads on average to a 5.10 percent appreciation from the previous month.

Our main novel results concern the effects of the liquidity yield on exchange rates. The coefficient estimates for  $\Delta \tilde{\eta}_{j,t}$  are all negative and statistically significant at the 1% level, with a range from -2.89 to -6.06. This indicates a 2.89% to 6.06% home currency appreciation in a month when there is a positive change of 100 basis points (annualized rate) in relative liquidity. We find that the relative government bond liquidity exhibits a very strong relationship with exchange rate movements for all the G-10 countries.

Table 1B displays the findings from estimation of the model using the  $\tilde{\eta}_t$  measure of the relative convenience yield as defined in equation (15). The results are almost identical to those of the baseline estimation in Table 1A, qualitatively, quantitatively, in precision of parameter estimates and in overall fit of the equation.

Tables 1A and 1B point to two important aspects of the impact of the liquidity yield. First, it is not just a U.S. dollar phenomenon. While a great deal of attention has been paid to the convenience yield on U.S. government bonds, our regression results show that the relative liquidity

<sup>&</sup>lt;sup>28</sup> See Engel (2014) for a recent survey.

yield is an important factor in explaining exchange rate changes for all of the G10 currencies. Further results reported in Table 1F (discussed below), and in section 3.4 emphasize this point.

However, secondly, the U.S. is still a special case in the sense that the impact of the relative convenience yields on the exchange rate is the largest in the U.S. The estimated coefficient on the liquidity yield is largest in absolute value for the U.S. (along with New Zealand), and the size of that impact is substantially larger than for most other currencies.

As a check on the reasonableness of the coefficient estimates in Table 1A, we can use the model for the estimating equation, (13), and the price adjustment equation, (6), to derive estimates of the structural parameters,  $\theta$ ,  $\sigma$ ,  $\psi$ ,  $\alpha$ ,  $\rho$  and  $\delta$ . We use the average first-order serial correlation of the real exchange rates for the G10 currencies to estimate  $\theta$ , and then the average estimates of  $\beta_i$ , i = 1,...,5 to estimate the other five parameters. Supplemental Appendix B4 describes the procedure in detail.

We find an unbiased estimate of  $\theta$  is 0.017, which gives the average half-life of the G10 real exchange rates as 40 months, consistent with Rogoff's (1996) estimate that the half-life of real exchange rates of major currencies is 3-5 years. We find the responsiveness of interest rates to inflation in the monetary policy rule,  $\sigma$ , of 4.69. While this is large compared to standard estimates, our monetary policy rule does not include an interest-rate smoothing term but instead incorporates persistence in the interest rate through serial correlation in the shocks to the policy rule. We estimate that serial correlation,  $\delta$ , as 0.964. The estimated value of  $(1-\delta)\sigma$  is 0.169, which is in line with estimates of the inflation responsiveness of interest rates to inflation in monetary rules that include interest-rate smoothing.

We estimate  $\alpha$  from equation (5), which captures the relation between the interest rate differential and the relative liquidity yield – the Nagel (2016) effect – to be 0.211. The measure of the reaction of interest rates to the liquidity yield in the monetary policy rule,  $\psi$ , from equation (7), is 0.241. Our estimates of  $\alpha$  and  $\psi$  are less than one, as in the model, and modest in size but not negligible. Finally, we find the serial correlation of the liquidity yield shocks,  $\rho$ , is 0.267.

All the structural parameter estimates are plausible, giving us some more confidence in our interpretation of the exchange-rate regression.

These parameters imply from the model equation (13) that the effects of  $\Delta \eta_{j,t}$  and  $\Delta i_{j,t}^{R}$ on the change in the log of the exchange rate will be similar. That is, the regression coefficients from the estimating equation (16) will be alike, and indeed in Table 1A, the average value (across the ten currencies) of  $\beta_2$  is -4.35 and of  $\beta_3$  is -5.10. If those coefficient estimates were identical, then we could consolidate the effects of  $\Delta \eta_{j,t}$  and  $\Delta i_{j,t}^R$  on the exchange rate into one variable,  $\Delta \eta_{j,t} + \Delta i_{j,t}^R = \Delta (IRS_t - IRS_t^*)$ . The currency value in this case appears to be driven only by the market interest rate differential and it might be tempting to simply add together the liquidity yield and the interest payments as two components of the return on investments in a country. But our results show that would be a mistaken approach because the strong statistical significance of both  $\Delta \eta_{j,t}$  and  $\Delta i_{j,t}^R$  tells us that there are independent forces driving the relative liquidity yield and government interest rate differentials that impact the exchange rate. The relationship between the market interest differential and exchange rates can be decomposed into separate effects, one driven primarily by liquidity shocks, and the other primarily by monetary policy.<sup>29</sup>

#### *Omitting the liquidity return*

For comparison, we also conduct the regression (16) but excluding the liquidity yield variables. That is:

(17) 
$$\Delta s_{j,t} = \alpha_j + \beta_1 q_{j,t-1} + \beta_2 (\Delta i_{j,t}^R) + \beta_3 (i_{j,t-1}^R) + u_{j,t},$$

The regression estimates are reported in Table 1C. The coefficient estimates on lagged real exchange rates and change in interest rate differential remain negatively significant for all country pairs. However, the within R-squared for this specification are universally much lower compared to Table 1A or 1B.<sup>30</sup> This indicates including relative government bond liquidity returns brings strong explanatory power to exchange rate determination, in addition to and independent of the traditional factors.

<sup>&</sup>lt;sup>29</sup> In Online Appendix A16, we report Table 1A regression but control for market interest rate rather than government bond interest rate.

<sup>&</sup>lt;sup>30</sup> The average R-squared in the baseline regression in Table 1B, which uses the same measure of the liquidity yield as Table 1C, is 0.150, but only 0.081 in the regressions that omit the liquidity yield.

#### *Estimation on sub-samples*

Next, we investigate whether the relationship between government bond liquidity and exchange rates are driven by 1) the Global Financial Crisis, 2) the post-crisis period or 3) only by the U.S. dollar. In Table 1D, we re-estimate the model but split the sample period into two periods, pre-2008 and post (and including)-2008. We see that the contemporaneous relationship between the change of the liquidity measure and the change of exchange rates holds in both time periods. As in the full sample, all the estimated coefficients on the impact of the estimated government liquidity return are negative. They are all individually statistically significant at the one percent level in the post-crisis period. In the pre-crisis data, the p-values for these coefficients are all less than 0.01 except for Japan and Switzerland but both of them still have a negative coefficient. The coefficient estimates in all cases have larger values in absolute terms after 2008, ranging from - 2.86 to -7.11. In addition to the significant and larger coefficients, the post-2008  $R^2$  are markedly improved, with a maximum of 33%, reflecting the importance of the relationship between the government bond liquidity and exchange rate determination.<sup>31</sup>

It is not the case that the results are driven by the global financial crisis years, 2007-2009. Table 1E reestimates the model using the full sample but excluding those crisis years. Compared to our baseline results, the findings excluding the crisis years are nearly identical.<sup>32</sup> The estimated coefficients on the change in  $\hat{\eta}_t$  and the change in  $i_t - i_t^*$  are very similar in magnitude to those we report in Table 1A, and all are statistically significant as in our baseline estimates. The error-correction terms for the adjustment of the nominal exchange rate to lagged real exchange rates is marginally statistically insignificant for Switzerland and the U.S. in this sample, and the overall fit of the model is not as good as indicated by generally lower values of the R-squared statistics. But the message of this table is that the principal findings are clearly not determined solely by the crisis years.

Table 1F displays estimates of the model that exclude the U.S. dollar from the sample. Each of the panel regressions is left with eight foreign currencies. We find that the relationship between government bond liquidity and exchange rates is largely unchanged. The coefficients on

<sup>&</sup>lt;sup>31</sup> In a country by country estimation of (16) reported in Online Appendix A6, the maximum  $R^2$  is 49%, which is the AUD – JPY pair.

<sup>&</sup>lt;sup>32</sup> Online Appendix A10 reports regressions that excludes 2000-2001 (dot com bubble and 9/11), 2007-2013 (GFC and European debt crisis). The main findings are robust to this.

the liquidity measure are negative and significant, though generally slightly smaller in absolute term than those estimated in Table 1A (except for JPY and GBP). The R-squared statistics are also largely unchanged. This exercise shows that our results are not simply a U.S. dollar phenomenon, instead observed in all currency pairs.<sup>33</sup> These findings do not preclude the view that the U.S. dollar is special, or that its convenience yield is central in the global economy, as in Bianchi et al. (2021) and Jiang et al. (2020, 2021). Apropos Verdelhan (2018), the U.S. convenience yield may be a significant factor driving exchange rates, and in our setting, the relationship between relative convenience yield of two non-U.S. countries, *i* and *j*, on the *ij* exchange rate might reflect the relative liquidity value of each country's bonds relative to the U.S. Treasury bonds. In other words, in a counterfactual world in which the U.S. is absent, country *i*'s bonds might be more liquid than country *j*'s, but in the actual world, country *j*'s might have a higher convenience yield because *i*'s bonds are a close substitute for U.S. bonds, while *j*'s offer some independent liquidity return.

#### One-month forward rates

As we have noted, in our baseline regressions we use one-year forward rates and one-year government yields as regressors, while the regressions are conducted in monthly frequency. The choice of one-year tenor is a tradeoff between model consistency and data availability. Ideally, for model consistency, we would use one-month forward rates and government yields to construct the variables. However, the data availability of one-month government yields is rather limited for some of the sample countries. In addition, in section 3.3, we use credit default swap (CDS) data to make an adjustment for the probability of non-repayment of government debt. The CDS data is more extensively available only for tenors of one year or above. Therefore, we use one-year forward rates and one-year government yields to construct the variables in our analysis. To be fully consistent with the model, investors would need to have no uncertainty about the one-month own-currency return on one-year bonds, but the variation in that return (annualized) relative to the one-year interest rate is very small relative to changes in exchange rate. The monthly correlation of one-year and one-month interest rates is over 0.90 in our sample for all countries.

<sup>&</sup>lt;sup>33</sup> Table 3B and Online Appendix A6 summarize and report the regression results country by country. Jiang et al. (2021) find a weaker relationship between the relative liquidity yield and non-U.S. exchange rates when the U.S. dollar is omitted from the study. We find that the main reasons for the differences in our findings are that we use monthly data rather than the quarterly data in Jiang et al., and that we estimate by panel methods, while Jiang et al. use univariate regressions of one currency relative to an average of the others. Online Appendix A details the effects of these differences.

Nevertheless, to make sure our result is robust to the choice of tenor, we report in Table 1G the regression coefficient estimates of equation (16), using one-month forward rates and onemonth government yield data.<sup>34</sup> The empirical relationship between the change of nominal exchange rate and the independent variables is largely consistent with the result we discussed in Table 1B, which uses one-year forward rates and one-year government yields data. Considering this, to make our empirical results comparable across different specifications, we use one-year forward rates and one-year government yields throughout the analysis.

#### Using survey measures of expectations

While uncertainty is an important driver of the liquidity yield, the question arises whether our findings arise simply because our measure of this relative convenience yield is a proxy for other deviations from uncovered interest parity, such as default risk or foreign exchange risk. Below, we control for default risk using CDS premiums. Also, our regressions include the interest rate differential as a separate variable, so if it is a risk premium at work, it must be a part of the risk premium that is uncorrelated with the interest rate differential. Here we undertake an exercise to see if there is an independent role for the relative liquidity premium.

Online Appendix A3 includes some estimates that incorporate a direct measure of the risk premium using the difference between forward rates and a survey measure of expected future exchange rates. Several recent studies have made use of data on exchange rate expectations of foreign exchange traders to measure the risk premium.<sup>35</sup> Our data on expectations come from the Bloomberg exchange rate forecasts. Letting  $s_{t,t+1}^e$  represent the time *t* expectation of the exchange rate at time t+1, the risk premium can be measured as:

$$rp_t = \dot{i}_t^* + s_{t,t+1}^e - s_t - \dot{i}_t$$

The risk premium augmented regression is

$$\Delta s_{j,t} = \alpha_j + \beta_1 q_{j,t-1} + \beta_2 \left( \Delta \tilde{\eta}_{j,t} \right) + \beta_3 \left( \Delta i_{j,t}^R \right) + \beta_4 \tilde{\eta}_{j,t-1} + \beta_5 i_{j,t-1}^R + \beta_6 \left( \Delta r p_{j,t} \right) + \beta_7 r p_{j,t-1} + u_{j,t-1} + \mu_{j,t-1} + \mu_{j,t-1}$$

<sup>&</sup>lt;sup>34</sup> Norway is excluded in this exercise as a home country and foreign country due to lack of Norway one-month government yield data.

<sup>&</sup>lt;sup>35</sup> Bussière et al. (2019), Chinn and Frankel (2020), Kalemli-Özcan (2019), Kalemli-Özcan and Varela (2019), Stavrakeva and Tang (2018, 2019),

We find that the change in the foreign risk premium does imply a home appreciation as theory would predict and is significant for all ten currencies. Importantly, the relative liquidity yield remains highly statistically significant in 9 of the 10 these regressions.

It is often argued in the literature that certain "safe haven" currencies (such as the U.S. dollar, the yen, or the Swiss franc) are less risky because their currencies appreciate during times of global turmoil. That relationship, however, does not explain why these currencies get stronger during global downturns. In Farhi and Gabaix (2015), marginal utilities of consumption in the safe-haven countries rise less than in other countries during such times, in turn because productivity declines are smaller in these countries. Gabaix and Maggiori (2015) build a model in which countries that are net debtors suffer a depreciation during times of global financial disruption, as financial intermediaries wish to unload debt securities as financial constraints tighten. As the paper notes, this conclusion runs counter to the evidence for the United States. In Gourinchas et al. (2017), during periods of weakness, markets fear even greater downturns in which government debt of some countries will default, which leads markets to find shelter in safer currencies. Perhaps the liquidity return story can complement the risk premium story by providing one other reason why some currencies are safe havens – because their government assets are more liquid, and therefore during global recessions demand for the safe haven currencies increases as the demand for liquidity rises.

#### *Emerging market currencies*

Our model and our empirical analysis is designed for analysis of low-inflation (e.g., inflation-targeting) countries with low default risk, as in the countries of the G10 currencies. We modify the model to extend our empirical analysis to emerging market currencies, focusing on eighteen emerging market currencies that Du, et al. (2018) dataset provides.<sup>36</sup> We report two specifications in Online Appendix A4. The first one takes an emerging market currency as the home country and the rest of the seventeen emerging market countries as the foreign countries. The second one takes the rest of the seventeen emerging market countries and all G10 currencies.

<sup>&</sup>lt;sup>36</sup> They are the more commonly traded currencies in the emerging market sample, including Brazilian Real (BRL), Chilean Peso (CLP), Chinese Yuan (CNY), Colombian Peso (COP), Hungarian Forint (HUF), Indonesian Rupiah (IDR), Israeli New Shekel (ILS), Indian Rupee (INR), Korean Won (KRW), Mexican Peso (MXN), Malaysian Ringgit (MYR), Peruvian Sol (PEN), Philippine Peso (PHP), Polish Zloty (PLN), Russian Ruble (RUB), South African Rand (ZAR), Thai Baht (THB), Turkish Lira (TRY).

as the foreign countries. To account for larger heterogeneity in emerging countries, we further control for inflation and default risk (using credit default swaps), and allow for different coefficients for home and foreign variables. <sup>37</sup> Our key finding of the importance of liquidity yield carries forward to the emerging market regressions. Coefficients of change of liquidity measure are estimated negative in 16 out of the 18 panels. 11 and 13 of them are significantly negative at 5% level in the two specifications. We also note that the coefficient estimates are generally smaller (in absolute value) for emerging markets. For those estimated negatively, they range from -0.003 (TRY) to -0.88 (RUB). This indicates a weaker role of Treasury bonds as a liquid and safe instrument in emerging markets.

We have seen so far that the inclusion of the liquidity variable greatly increases the explanatory power of the model for all G10 currencies, and the model is not very sensitive to estimation over sub-samples of the time span of our data, or to alternative measures of the relative convenience yield. We next dig deeper into the data to get a better understanding of what drives these results.

### 3.3 Decomposing the Liquidity Measure

In this section, we decompose the relative liquidity measure to assess the impact of three components on exchange rate movements: deviations from covered interest parity for interest rate swaps,  $\tau_t \equiv f_{t,t+1} - s_t + IRS_t^* - IRS_t$ ; the difference between home and foreign credit default swap premiums,  $l_t^R = CDS_t - CDS_t^*$ ; and the relative liquidity yield, corrected for default swap premiums,  $\lambda_t = IRS_t - i_t - (IRS_t^* - i_t^*) + l_t^R$ .<sup>38</sup>

In relation to our previous measures,  $\hat{\eta}_t$  from equation (14) is given by:

(18)  $\hat{\eta}_t = \lambda_t - l_t^R$ ,

and  $\tilde{\eta}_t$  from equation (15) is given by:

(19) 
$$\tilde{\eta}_t = \hat{\eta}_t + \tau_t = \lambda_t - l_t^R + \tau_t.$$

<sup>&</sup>lt;sup>37</sup> See section 3.3 for a more detailed discussion on accounting for default risk in the liquidity measure.

<sup>&</sup>lt;sup>38</sup> Details of the full derivation of these expressions are available at Du, et al. (2018a).

First, the government bond yields might incorporate expected default risk. A credit default swap (CDS) contract insures the buyer against credit events. In the case of sovereign default, the CDS sellers make payments to the buyers to compensate for the loss in the credit event. Buyers of the CDS pay a premium to CDS sellers for the insurance. The return to a riskless home government bond – that is, a home government bond protected by insurance – is therefore  $i_t - CDS_t$ , where  $CDS_t$  is the CDS premium. To measure the relative convenience yield, we therefore adjust the interest rate on government bonds to get the true riskless return. Then  $\lambda_t$  can be understood as the relative government bond convenience yield after adjusting for credit default risk.

The home minus foreign difference of CDS premium is a measure of the relative premium investors are willing to pay to avoid default, i.e.  $l_{j,t}^R = CDS_t - CDS_{j,t}^*$ . Della Corte, et al. (forthcoming) examine the effects of sovereign default on exchange rates. When  $l_{j,t}^R > 0$ , investors are willing to pay more for protection against home default compared to foreign default. When  $\Delta l_{j,t+1}^R > 0$ , there is an increase in home default risk relative to foreign default risk which we posit is associated with an immediate home currency depreciation. From one perspective, an increase in  $l_{j,t}^R$ , holding the nominal government bond interest rate fixed, simply implies that the return on home bonds falls because of the increase in the cost of the CDS.<sup>39</sup> Alternatively, as Della Corte et al. (forthcoming) demonstrate, an increase in the CDS rate reflects an increase in default probability and in default risk, which leads to a depreciation of the currency as its sovereign bonds are both riskier and offer lower expected returns.

The third component is the deviation from covered interest parity. If covered interest parity held for market returns, we should find  $f_{t,t+1} - s_t + IRS_t^* = IRS_t$ , where  $IRS_t$  ( $IRS_t^*$ ) refers to the home (foreign) return on LIBOR swaps. Baba et al. (2008), Baba and Packer (2009), and Griffoli and Ranaldo (2011) attribute the failure of covered interest arbitrage in the years immediately following the global financial crisis to both a liquidity and a default factor. In particular, there appeared to be profitable arbitrage opportunities that involved borrowing in dollars and making covered investments in foreign interest-earning assets. These papers provide evidence that investors were reluctant to take advantage of such opportunities both because of counterparty risk,

<sup>&</sup>lt;sup>39</sup> See Online Appendix B7 for a more detailed discussion of the model solution with default risk.

and because there was a global demand for liquid dollar assets. Du, et al. (2018b) find that in recent years, for some currencies (particularly, when the U.S. dollar is the home currency),  $IRS_t < f_{t,t+1} - s_t + IRS_t^*$ , but financial institutions do not undertake the arbitrage that would result in riskless profits. In order to earn those profits, banks would need to go short in dollars, and purchase the foreign currency on the spot market and go long in foreign currency (which they sell forward.) Such an arbitrage investment, while risk free, expands the size of the financial institutions' balance sheets, and may cause them to run afoul of regulatory constraints. Financial institutions that held home assets could sell those and acquire synthetic home assets, but they might be unwilling to do so if they value the home assets for non-pecuniary reasons. Hence, when home assets are especially valued, then  $\tau_t$  will be high, and the home currency will be strong. The same relationship could arise if there were default risk on LIBOR rates, as might have been the case in 2008 during the global financial crisis. When foreign LIBOR is considered risky,  $\tau_t$  is high, and the home currency is strong. We note that Cerutti, et al. (2021) associate the failure of covered interest parity for the U.S. dollar with periods of a strong dollar.<sup>40</sup>

Jiang et al. (2020, 2021) interpret  $\tau_t$  as a convenience yield on home (U.S.) LIBOR. That is,  $f_{t,t+1} - s_t + IRS_t^*$  denotes the return on a foreign LIBOR, swapped into dollars. If this return is greater than  $IRS_t$ , so that  $\tau_t > 0$ , the home LIBOR pays a lower return because of its liquidity relative to the liquidity of the foreign LIBOR that is swapped into dollars in the forward market. So, conceptually, we have two different sorts of convenience yields.  $\tau_t$  is the convenience yield of home LIBOR relative to foreign LIBOR, while  $\hat{\eta}_t$  is the convenience yield on the home government bond compared to the market rate, relative to the analogous convenience yield in the foreign country.

In all cases, we use IRS and CDS data with one-year tenor as the CDS data are extensively available only for tenors of one-year or above.

With these decomposed components, we modify the baseline regression by putting each into the equation. Specifically,

<sup>&</sup>lt;sup>40</sup> See. Du, et al. (2018b) investigate deviations from covered interest parity and Avdjiev, et al. (2018) consider the relationship between the currency swap friction and the exchange rate.

(20) 
$$\Delta s_{j,t} = \alpha_j + \beta_1 q_{j,t-1} + \beta_2 \Delta \lambda_{j,t} + \beta_3 \Delta \tau_{j,t} + \beta_4 \Delta l_{j,t}^R + \beta_5 \Delta i_{j,t}^R + \beta_6 \lambda_{j,t-1} + \beta_7 \tau_{j,t-1} + \beta_8 l_{j,t-1}^R + \beta_9 i_{j,t-1}^R + u_{j,t}$$

As discussed above, we expect to find a negative estimate of  $\beta_3$ , because a larger  $\Delta \tau_{j,t}$  indicates an unwillingness to sell home assets to buy the foreign currency, which appreciates the home currency. The estimated  $\beta_4$  should be positive, since a larger  $\Delta l_{j,t}^R$  means there is a greater default risk for home government bonds.  $\Delta \lambda_{j,t}$  is the residual measure of the change in the home relative to foreign liquidity yields, and for that we posit a negative value of  $\beta_2$ . As in our model, we should also find negative values for the estimates of  $\beta_1$  and  $\beta_5$ .

We estimate the regression in two ways. First, since CDS data for many of the sample countries are only available after 2008, we start the sample from 2008M1 and estimate (20). Second, to make use of the full sample information and test whether the adjusted liquidity measure is important in explaining the change of exchange rates throughout the sample, we estimate the regression from 1999M1, but excluding the CDS variables (dropping  $\Delta l_{j,t}^R$  and  $l_{j,t-1}^R$ ).<sup>41</sup>

In Table 2A, the coefficient estimates on  $\Delta \lambda_{i,t}$ , which represents the effect of changes in government bond liquidity after adjusting for credit risk and derivative market friction, are still significantly negative in all cases. The range of coefficient is from -3.04 to -8.91 for the left panel, indicating a monthly 3.04% to 8.91% immediate home currency appreciation when there is a monthly positive change of 100 basis points (annualized rate) in relative liquidity. These coefficients are also larger than the coefficients of  $\Delta \eta_{i,t}$  estimated in Table 1A or Table 1B. These results reaffirm our baseline result that there is a strong linkage between government bond liquidity and exchange rates.

In many cases, we also see that credit risk variation and derivative market frictions are important variables in explaining the change of exchange rates.<sup>42</sup> The positive coefficient on  $\Delta l_{j,t}^{R}$ indicates that an increase in home default risk relative to foreign default risk is associated with an

 $<sup>^{41}</sup>$  In the second case, the  $\lambda_{_{j,t}}$  is effectively  $\eta_{_{j,t}} - au_{_{j,t}}$ 

<sup>&</sup>lt;sup>42</sup> See Della Corte, et al. (forthcoming) who find similar findings of the relationship between exchange rate and sovereign risk.

immediate home currency depreciation. Holding the nominal government bond interest rate fixed, an increase in default risk implies the default risk adjusted nominal interest rate goes down, resulting in a home currency depreciation. The negative coefficient on  $\Delta \tau_{j,t}$  can be interpreted as the influence of an increase in the convenience yield on home bonds relative to foreign bonds. The channel could go through default risk on interest rate swaps, or there may be a liquidity yield of the home currency asset.

To confirm our results are robust to different specifications, we conduct the estimation in (20) by including one or two sub-components at a time. The results are reported at Table 2B. Once again, we find the regression coefficients for  $\Delta \lambda_{i,t}$  are significantly negative in all cases.

How much of the variation of  $\tilde{\eta}_t$  is driven by each of the sub-components? We can answer this with a variance decomposition. Table 2C reports the decomposition given by:

$$(21) \quad 1 = \frac{\operatorname{var}(\Delta\lambda_t)}{\operatorname{var}(\Delta\tilde{\eta}_t)} + \frac{\operatorname{var}(\Delta\tau_t)}{\operatorname{var}(\Delta\tilde{\eta}_t)} + \frac{\operatorname{var}(\Delta l_t^R)}{\operatorname{var}(\Delta\tilde{\eta}_t)} + 2\frac{\operatorname{cov}(\Delta\lambda_t, \Delta\tau_t)}{\operatorname{var}(\Delta\tilde{\eta}_t)} - 2\frac{\operatorname{cov}(\Delta\tau_t, \Delta l_t^R)}{\operatorname{var}(\Delta\tilde{\eta}_t)} - 2\frac{\operatorname{cov}(\Delta l_t^R, \Delta\lambda_t)}{\operatorname{var}(\Delta\tilde{\eta}_t)} - 2\frac{\operatorname{cov}(\Delta\tau_t, \Delta l_t^R)}{\operatorname{var}(\Delta\tilde{\eta}_t)} - 2\frac{\operatorname{cov}(\Delta\tau_t, \Delta l_t^R)}{\operatorname{var}(\Delta\tilde{\eta}_t)} - 2\frac{\operatorname{cov}(\Delta\tau_t, \Delta\lambda_t)}{\operatorname{var}(\Delta\tilde{\eta}_t)} - 2\frac{\operatorname{var}(\Delta\tilde{\eta}_t)}{\operatorname{var}(\Delta\tilde{\eta}_t)} - 2\frac{\operatorname{var}(\Delta\tilde{\eta}_t$$

For most of the countries, the variation of  $\Delta \lambda_t$  contributes a large share of variation of  $\Delta \tilde{\eta}_t$ . However, the sums of the variance shares of  $\Delta \lambda_t$ ,  $\Delta \tau_t$ , and  $\Delta l_t^R$  are greater than one. This arises because of the negative correlation of  $\Delta \lambda_t$  with  $\Delta \tau_t$  and  $-\Delta l_t^R$ . We see that even controlling for default and swap-market frictions, the liquidity yield is still a significant determinant of exchange rates.

#### 3.4 Country-specific Government Bond Liquidity

So far, we have conducted all our analysis with different measures of bilateral relative government bond liquidity. However, the impact of the own-country liquidity service and the aggregate foreign country liquidity service might have different effects on the home exchange rate.

We measure the home and foreign liquidity returns on government bonds as  $\gamma_t = IRS_t - i_t$ and  $\gamma_{j,t}^* = IRS_t^* - i_t^*$ . Motivated by the decomposition above, we will include also the currency derivative market friction,  $\tau_{j,t}$ . We have then decomposed  $\tilde{\eta}_{j,t}$  used in our baseline regressions:

(22) 
$$\tilde{\eta}_{j,t} = \tau_{j,t} + \gamma_t - \gamma_{j,t}^*$$

We estimate the following equation with the country specific liquidity measures, controlling for the derivative market friction:

(23)

 $\Delta s_{j,t} = \alpha_j + \beta_1 q_{j,t-1} + \beta_2 \Delta \tau_{j,t} + \beta_3 \Delta \gamma_t + \beta_4 \Delta \gamma_{j,t}^* + \beta_5 \Delta i_{j,t}^R + \beta_6 \tau_{t-1} + \beta_7 \gamma_{t-1} + \beta_8 \gamma_{j,t-1}^* + \beta_9 i_{j,t-1}^R + u_{j,t}$ Estimates of  $\beta_3$  and  $\beta_4$  in (23) show how the change of country-specific government bond liquidity affects exchange rate movements. We expect a negative sign for  $\beta_3$  and a positive sign for  $\beta_4$ .

Table 3A presents the estimation results for the country specific government bond liquidity. The second column gives the coefficient estimates for the change in government bond liquidity for all the foreign currencies. The coefficient estimates are all significantly positive, indicating an increase in government bond liquidity of the foreign country is associated with a depreciation of the home currency, which is consistent with our theory and the empirical finding above. All the coefficient estimates of the home government bond liquidity,  $\Delta \gamma_t$ , term are significantly negative with the exception of the Japanese Yen and Swiss Franc. Both estimates are negative but with smaller absolute size compared to others.

These results then show that our findings regarding the effect of the relative liquidity returns on exchange rates are, for each country, driven at least in part by the liquidity return of that country. That is, the effects on exchange rates of the relative liquidity returns are not all determined by liquidity returns in one or a few larger countries.

We provide further evidence that our findings are not driven by one or a few countries by performing our baseline regression (16) country-by-country. Table 3B provides a summary of those regression results. (We report all 45 country-by-country regressions in Online Appendix A6.) For the analysis that uses the entire 1999-2018 sample, among the 45 country pairs, 37 country pairs have coefficients on  $\Delta \tilde{\eta}_t$  that are negatively statistically different from zero at the 10% level. We find that 42 of the 45 pairs have a negatively significant coefficient on  $\Delta i_t^R$  at the 1% level. This evidence makes manifest that our results are not driven by a single country. Country-bycountry regressions also allow the coefficients to be unconstrained and leave room for higher explanatory power. While the median adjusted R-squared of the full sample regressions (17%) is close to the average R-squared of the panel regressions, the maximum adjusted R-squared is 33% for the full sample and 49% post-2008 (in both cases for the AUD-JPY pair).

#### 3.5 Out-of-sample fit

The influential work by Meese and Rogoff (1983) shows that standard macroeconomic exchange rate models, even with the aid of ex post data on the fundamentals, forecast exchange rates at short to medium horizons no better than a random walk. In this subsection, we conduct an out-of-sample forecasting exercise as in Meese and Rogoff (1983) and find that our empirical model significantly outperforms the random walk prediction.<sup>43</sup>

We estimate (17), the model with only interest rate differential and the lagged real exchange rate as explanatory variables, and (16), the empirical model that also includes the liquidity return, using a rolling regression approach. We first use the sample from 1999M1 to 2007M12 for the estimation of regression coefficients. <sup>44</sup> The rolling window is therefore 108 months and the forecast horizon is one month. The first prediction is 2008M1 and the last prediction is 2018M1. We then compare the root-mean-square-error (RMSE) of these models verse the RMSE of a random walk no change prediction ( $\Delta \hat{s}_{j,t}^{RW} = 0$ ). As in the Meese-Rogoff exercise, we use actual realized values of the right-hand-side variables to generate the forecasts.

Table 4 reports the RMSEs of the predictions of models (16), (17) and the random walk prediction. The RMSEs of forecasts from (16) and (17) are lower than the RMSEs of the random walk prediction in 9 out of the 10 countries. We are also interested in testing whether these differences in RMSEs are statistically significant. We adopt the test statistics by Diebold and Mariano (1995) and West (1996) (DMW) which tests the following three null hypothesis: A) mean-square-error (MSE) of the prediction model (17) and the random walk model are equal, B) MSE of the prediction model (16) and the random walk model are equal and C) MSE of the prediction model (17) and MSE of the prediction model (16) are equal. The DMW statistics are

<sup>&</sup>lt;sup>43</sup> Engel and Wu (2021) considers pitfalls in assessing the forecastability of the U.S. dollar in the 21<sup>st</sup> century using various recently proposed predictive variables.

<sup>&</sup>lt;sup>44</sup> We provide robustness of different end date for estimation of regression coefficients (ends at 2005M12 and 2009M12. We also estimate using a recursive regression approach. The results are robust both and are reported in Online Appendix A13.

reported in column (5)-(7) in Table 4. Since model (16) nests model (17) and the random walk model, Clark and West (2006) shows that the DMW test statistic should be corrected to account for the fact the regression coefficients are estimated. The Clark-West adjusted test statistic (CW statistics) is asymptotically standard normal and suitable for usual statistics inference. We report the CW statistics and the corresponding p-value of the one-sided alternative test in columns (8)-(14). We find that the prediction model (17), which includes only the lagged real exchange rate and the interest-rate differential, performs significantly better than random walk in 9 out of the 10 cases (p-values in column (9).) We find the baseline model with liquidity returns, (16), outperforms the random walk model in nine cases (p values in column (11).) In nine cases, we find that the MSE of model (16) are significantly lower than model (17) (p-values in column (13).) Thus, the random-walk model and the model that does not include liquidity returns are rejected in favor of our baseline model for nine currencies, except for CHF, using the Meese-Rogoff criterion.

## Switzerland, January 2015

The model with the liquidity yield included significantly outperforms the random walk model and the traditional model for almost all currencies, but the RMSE for both the liquidity model and the traditional model are higher than the random walk for the single exception of Switzerland.<sup>45</sup> If we eliminate one month from the Swiss sample, January 2015, the models also have lower RMSEs than the random walk.

Until that month, the Swiss National Bank had been trying to keep the Swiss franc from appreciating, setting very low interest rates and engaging in massive foreign exchange intervention to keep a ceiling on the value of the franc of CHF1.20 per euro. The SNB lifted the cap in January 2015, which led to a very large franc appreciation that month, despite the low Swiss interest rates. The model performs poorly in that month because the low interest rates should have led to a depreciation of the franc, as the SNB desired.

In fact, all our results reported in previous table are improved, sometimes markedly, for the Swiss franc if that one month is eliminated from the sample. It is an extreme outlier. <sup>46</sup> The absolute value of the change in the log of the exchange rate during that month is much greater than

<sup>&</sup>lt;sup>45</sup> Note that because the CW statistic takes into account estimation error, both models are found to have a positive value of CW statistic, even including January 2015, even though their RMSEs are higher than the random walk model's RMSE.

<sup>&</sup>lt;sup>46</sup> In Online Appendix A11, we report the results with the extreme outlier in January 2015 dropped.

for any currency during any month, and it is also a month in which Swiss interest rates were at extremely low values. In particular, in a few of the regressions reported above, the sign on the interest differential was positive rather than negative for Switzerland, but that anomaly disappears when January 2015 is dropped from the sample.

#### 4. Conclusions

Our empirical findings are good news for macroeconomic models of exchange rates. The government liquidity yield is the "missing link" in exchange rate determination. Not only do we find that liquidity yields are a significant determinant of exchange rate movements for all the largest countries, but we also find that with these included, traditional determinants of exchange rate movements are also important. Our simple regressions have high R-squared values, so can account for a large fraction of exchange rate movements. Our empirical specification is based on a model that is a straightforward extension of the canonical open-economy New Keynesian model to allow for liquidity yields.

An important next step is to dig deeper into the origins of the liquidity yield. Does it arise because government bonds are useful as collateral, perhaps because the market can assess their value without any fear that the counterparty has private information? Or because markets for government bonds are deeper, and therefore more liquid in the traditional sense that they are assets that are less expensive to buy and sell? Or perhaps for some reason, our measure of the liquidity yield is correlated with some other fundamental driver, such as a foreign exchange risk premium that is, in fact, the true driving variable for foreign exchange rates. These possibilities suggest avenues for further theoretical and empirical research.

Table 1A: Estimation result of baseline panel regression using interest rate swaps to construct liquidity measure

 $\Delta s_{j,t} = \alpha_j + \beta_1 q_{j,t-1} + \beta_2 \Delta \hat{\eta}_{j,t} + \beta_3 \Delta i_{j,t}^R + \beta_4 \hat{\eta}_{j,t-1} + \beta_5 i_{j,t-1}^R + u_{j,t}$ 

The table reports the OLS estimates of the coefficient of the panel fixed effect regression listed above. The 10 currencies used are Australian Dollar (AUD), Canadian Dollar (CAD), Euro (EUR), Japanese Yen (JPY), New Zealand Dollar (NZD), Norwegian Krone (NOK), Swedish Krona (SEK), Swiss Franc (CHF), British Pound (GBP) and United States Dollar (USD). Each row represents a regression estimation using the first column currency as the home currency and the other 9 currencies as foreign currency j.  $s_{j,t}$  is the nominal exchange rate between home and foreign country j, defined as home currency price of foreign currency,  $q_{j,t}$  is the real exchange rate.  $\hat{\eta}_i$  is the measure of government bond liquidity,  $i_{j,t}^R$  is the home minus foreign interest rates.  $\Delta$  is a difference operator. The sample period is 1999M1-2018M1.

Standard errors in parentheses are standard errors adjusted for cross-sectional correlation. \*, \*\*, and \*\*\* indicate that the alternative model significantly different from zero at 10%, 5%, and 1% significance level, respectively, based on standard normal critical values for the two-sided test

Table 1B:

Estimation result of baseline panel regression with baseline liquidity measure

Estimation result of panel regression with decomposed liquidity measure

The table reports the OLS estimates of the coefficient of the panel fixed effect regression listed above. The 10 currencies used are Australian Dollar (AUD), Canadian Dollar (CAD), Euro (EUR), Japanese Yen (JPY), New Zealand Dollar (NZD), Norwegian Krone (NOK), Swedish Krona (SEK), Swiss Franc (CHF), British Pound (GBP) and United States Dollar (USD). Each row represents a regression estimation using the column (1) currency as the home currency and the other 9 currencies as foreign currency j.  $s_{j,t}$  is the nominal exchange rate between home and foreign country j, defined as home currency price of foreign currency,  $q_{j,t}$  is the real exchange rate.  $\tau_{i,t}$  is the measure of currency derivative friction,  $l_{i,t}^{R}$  is the measure of home minus foreign default risk,

 $\lambda_{i,t}$  is the measure of the government bond liquidity after adjusting for derivative market friction and default risk,  $i_{j,t}^R$  is the home

minus foreign interest rates. Å is a difference operator. The sample period is 1999M1-2018M1 (column (2) to (4)) and 2008M1-2018M1 (column (5) to (8)). Germany government interest rate and default risk are used for EUR case.

Standard errors in parentheses are standard errors adjusted for cross-sectional correlation. \*, \*\*, and \*\*\* indicate that the alternative model significantly different from zero at 10%, 5%, and 1% significance level, respectively, based on standard normal critical values for the two-sided test.

within $R^2$						

where  $X_{i,t}$  is the column head variable

The table reports the OLS estimates of the coefficient of change of liquidity measure of the regression listed above. The 10 currencies used are Australian Dollar (AUD), Canadian Dollar (CAD), Euro (EUR), Japanese Yen (JPY), New Zealand Dollar (NZD), Norwegian Krone (NOK), Swedish Krona (SEK), Swiss Franc (CHF), British Pound (GBP) and United States Dollar (USD). Each row represents a regression estimation using the column (1) currency as the home currency and the other 9 currencies as foreign currency *j*.  $s_{j,t}$  is the nominal exchange rate between home and foreign country *j*, defined as home currency price of foreign currency,  $q_{j,t}$  is the real exchange rate.  $\tau_{j,t}$  is the measure of currency derivative friction,  $l_{j,t}^{R}$  is the measure of home minus foreign default risk,  $\lambda_{j,t}$  is the measure of the government bond liquidity after adjusting for derivative market friction and

default risk,  $i_{j,t}^R$  is the home minus foreign interest rates.  $\Delta$  is a difference operator. The sample period is 1999M1-2018M1. Regressions involving default risk  $l_{j,t}^R$  are only estimated through 2008M1-2018M1 period (column (2), (4), (5),(7)). Germany default risk is used for EUR case.

Standard errors in parentheses are standard errors adjusted for cross-sectional correlation. \*, \*\*, and \*\*\* indicate that the alternative model significantly different from zero at 10%, 5%, and 1% significance level, respectively, based on standard normal critical values for the two-sided test.

Estimation result of panel regression with country-specific liquidity measure

The table reports the OLS estimates of the coefficient of the panel fixed effect regression listed above. The 10 currencies used are Australian Dollar (AUD), Canadian Dollar (CAD), Euro (EUR), Japanese Yen (JPY), New Zealand Dollar (NZD), Norwegian Krone (NOK), Swedish Krona (SEK), Swiss Franc (CHF), British Pound (GBP) and United States Dollar (USD). Each row represents a regression estimation using the column (1) currency as the home currency and the other 9 currencies as foreign currency j.  $s_{j,t}$  is the nominal exchange rate between home and foreign country j, defined as home currency price of foreign currency,  $q_{j,t}$  is the real exchange rate.  $\tau_{j,r}$  is the measure of currency derivative friction,  $\hat{\gamma}_{j,t}^*$  is the measure of foreign government bond

liquidity,  $\hat{\gamma}_{j,t}$  is the measure of the home government bond liquidity,  $i_{j,t}^R$  is the home minus foreign interest rates.  $\Delta$  is a difference operator. The sample period is 1999M1-2018M1. Germany government interest rate is used for EUR case.

Standard errors in parentheses are standard errors adjusted for cross-sectional correlation. \*, \*\*, and \*\*\* indicate that the alternative model significantly different from zero at 10%, 5%, and 1% significance level, respectively, based on standard normal critical values for the two-sided test.

and random walk (RW) model: 
$$\Delta \hat{s}_{j,t}^{RW} = 0$$

The 10 currencies used are Australian Dollar (AUD), Canadian Dollar (CAD), Euro (EUR), Japanese Yen (JPY), New Zealand Dollar (NZD), Norwegian Krone (NOK), Swedish Krona (SEK), Swiss Franc (CHF), British Pound (GBP) and United States Dollar (USD). Each row represents a rolling window predictive regression using the column (1) currency as the home currency and the other 9 currencies as foreign currency *j*.  $s_{j,t}$  is the nominal exchange rate between home and foreign country *j*, defined as home currency price of foreign currency,  $q_{j,t}$  is the real exchange rate.  $\tilde{\eta}_i$  is the measure of government bond liquidity,  $i_{l,t}^R$  is the home

minus foreign interest rates.  $\Delta$  is a difference operator. The rolling window is 108 months. The first estimated coefficient uses sample from 1999M1 to 2007M12. Germany government interest rate is used for EUR case. DMW stands for Diebold and Mariano (1995) and West (1996) and CW stands for Clark and West (2007).

The null hypotheses are that the models MSE are equal. The alternative hypotheses are that the larger models MSE are smaller than the nested models. \*, \*\*, and \*\*\* indicate that the alternative model significantly outperforms the smaller nested model at 10%, 5%, and 1% significance level, respectively, based on standard normal critical values for the one-sided test. Standard errors adjusted for cross-sectional correlation.

A3 Summary Statistics

#### **Appendix A1 Derivation of Model of Liquidity Returns**

Consider first the problem of the home-country investor. As in Krishnamurthy and Vissing-Jorgensen (2012), Nagel (2016) and Engel (2016), we take a very simple approach to modeling the liquidity service of some assets, by including them in the utility function. In particular, we assume home households maximize:

(B.1) 
$$E_0\left\{\sum_{t=0}^{\infty}\beta^t\left[u\left(c_t\right)+v\left(\frac{M_{H,t}}{P_t},\frac{B_{H,t}}{P_t},\frac{S_tB_{H,t}^*}{P_t}\right)\right]\right\}$$

There are six assets in the world economy:

 $M_t$  - home country money

 $M_t^*$  - foreign country money

 $B_t$  - home country government bonds

 $B_t^*$  - foreign country government bonds

 $B_t^m$  - home country "market" bonds

 $B_t^{*m}$  - foreign country "market" bonds

The H subscript in the asset holdings refers to home country holdings of each asset, while F will denote foreign country holdings.  $c_t$  ( $c_t^*$ ) is home (foreign) country consumption.

The utility function for the home household shows that it may get liquidity services from home money, home government bonds and foreign government bonds. We require that holdings of each of these assets must be weakly positive. We will assume that the supplies of the assets and the parameterization of the utility function is such that the home household will always hold home money and government bonds and get liquidity services from those assets, but it may hold a zero amount of foreign government bonds in equilibrium. The utility function v(.) is assumed to be concave, but Inada conditions do not hold for the foreign government bond, so its holdings may be zero. Furthermore, we will follow Nagel (2016) and assume that home bond are a perfect substitute for  $\kappa$  units of money,  $0 < \kappa < 1$ . An example of such a utility function is:

(B.2) 
$$v\left(\frac{M_{H,t}}{P_t}, \frac{B_{H,t}}{P_t}, \frac{S_t B_{H,t}^*}{P_t}\right) = \frac{1}{1-\gamma} \left[ \left(\frac{M_{H,t} + \kappa B_{H,t}}{P_t}\right)^{\frac{\varepsilon-1}{\varepsilon}} + \left(\frac{\eta S_t B_{H,t}^*}{P_t} + \mu\right)^{\frac{\varepsilon-1}{\varepsilon}} \right]^{\frac{(1-\gamma)\varepsilon}{\varepsilon-1}}$$

where we assume  $\varepsilon > 1$ ,  $\gamma > 0$ ,  $0 < \kappa < 1$ ,  $0 < \eta < 1$ ,  $\mu \ge 0$ .

This specification is a slight generalization of that of Nagel (2016) because we assume that there are two non-money assets that might deliver liquidity services.

The period-by-period budget constraint is given by

(B.3) 
$$P_{t}c_{t} + M_{H,t} + B_{H,t} + B_{H,t}^{m} + S_{t}B_{H,t}^{*} + S_{t}B_{H,t}^{*m}$$
  
$$= P_{t}y_{t} + M_{H,t-1} + (1+i_{t-1})B_{H,t-1} + (1+i_{t-1}^{m})B_{H,t-1}^{m} + S_{t}(1+i_{t-1}^{*})B_{H,t-1}^{*} + S_{t}(1+i_{t-1}^{*m})B_{H,t-1}^{*m}$$

Households maximize (B.1) subject to (B.3), and to the constraints  $M_{H,t} \ge 0$ ,  $B_{H,t} \ge 0$  and  $B_{H,t}^* \ge 0$ . These latter constraints mean that households are unable to issue securities with the same liquidity properties as government securities.

We will assume, for convenience, that as in the New Keynesian model in the paper, goods prices in each currency are known one period in advance. The first-order conditions are given by:

$$(B.4) \quad -\frac{1}{P_{t}}u'(c_{t}) + \frac{1}{P_{t+1}}\beta E_{t}u'(c_{t+1}) + \frac{1}{P_{t}}v_{M}\left(\frac{M_{H,t}}{P_{t}}, \frac{B_{H,t}}{P_{t}}, \frac{S_{t}B_{H,t}^{*}}{P_{t}}\right) \leq 0$$

$$(B.5) \quad -\frac{1}{P_{t}}u'(c_{t}) + \frac{1+i_{t}}{P_{t+1}}\beta E_{t}u'(c_{t+1}) + \frac{1}{P_{t}}\kappa v_{M}\left(\frac{M_{H,t}}{P_{t}}, \frac{B_{H,t}}{P_{t}}, \frac{S_{t}B_{H,t}^{*}}{P_{t}}\right) \leq 0$$

$$(B.6) \quad -\frac{1}{P_{t}}u'(c_{t}) + \frac{1+i_{t}^{*}}{P_{t+1}}\beta E_{t}u'(c_{t+1}) = 0$$

$$(B.7) \quad -\frac{S_{t}}{P_{t}}u'(c_{t}) + \frac{1+i_{t}^{*}}{P_{t+1}}\beta E_{t}S_{t+1}u'(c_{t+1}) + \frac{S_{t}}{P_{t}}v_{B^{*}}\left(\frac{M_{H,t}}{P_{t}}, \frac{B_{H,t}}{P_{t}}, \frac{S_{t}B_{H,t}^{*}}{P_{t}}\right) \leq 0$$

$$(B.8) \quad -\frac{S_{t}}{P_{t}}u'(c_{t}) + \frac{1+i_{t}^{*}}{P_{t+1}}\beta E_{t}S_{t+1}u'(c_{t+1}) = 0$$

The foreign household's problem is symmetric. The first-order conditions for the foreign household are:

$$(B.9) \quad -\frac{1}{P_{t}^{*}}u'(c_{t}^{*}) + \frac{1}{P_{t+1}^{*}}\beta E_{t}u'(c_{t+1}^{*}) + \frac{1}{P_{t}^{*}}v_{M^{*}}^{*}\left(\frac{M_{F,t}^{*}}{P_{t}^{*}}, \frac{B_{F,t}^{*}}{P_{t}^{*}}, \frac{S_{t}^{-1}B_{F,t}}{P_{t}^{*}}\right) \leq 0$$

$$(B.10) \quad -\frac{1}{P_{t}^{*}}u'(c_{t}^{*}) + \frac{1+i_{t}^{*}}{P_{t+1}^{*}}\beta E_{t}u'(c_{t+1}^{*}) + \frac{1}{P_{t}^{*}}\kappa v_{M^{*}}^{*}\left(\frac{M_{F,t}^{*}}{P_{t}^{*}}, \frac{B_{F,t}^{*}}{P_{t}^{*}}, \frac{S_{t}^{-1}B_{F,t}}{P_{t}^{*}}\right) \leq 0$$

$$(B.11) \quad -\frac{1}{P_{t}^{*}}u'(c_{t}^{*}) + \frac{1+i_{t}^{*m}}{P_{t+1}^{*}}\beta E_{t}u'(c_{t+1}^{*}) = 0$$

$$(B.12) \quad -\frac{S_{t}^{-1}}{P_{t}^{*}}u'(c_{t}^{*}) + \frac{1+i_{t}}{P_{t+1}^{*}}\beta E_{t}S_{t+1}^{-1}u'(c_{t+1}^{*}) + \frac{S_{t}^{-1}}{P_{t}^{*}}v_{B}^{*}\left(\frac{M_{F,t}^{*}}{P_{t}^{*}}, \frac{B_{F,t}^{*}}{P_{t}^{*}}, \frac{S_{t}^{-1}B_{F,t}}{P_{t}^{*}}\right) \leq 0$$

$$(B.13) \quad -\frac{S_{t}^{-1}}{P_{t}^{*}}u'(c_{t}^{*}) + \frac{1+i_{t}}{P_{t+1}^{*}}\beta E_{t}S_{t+1}^{-1}u'(c_{t+1}^{*}) = 0$$

Equations (B.6) and (B.8) imply the relationship:

$$(1+i_t^m)E_tu'(c_{t+1})=(1+i_t^{*m})E_t\frac{S_{t+1}}{S_t}u'(c_{t+1})=0.$$

If we maintain the assumption of rational expectations and no market frictions, then the assumption that the conditional distribution of exchange rates and consumption is jointly lognormal, we can derive

$$i_t^{*m} + E_t s_{t+1} - s_t - i_t^m = -\frac{1}{2} \operatorname{var}_t (s_{t+1}) - \operatorname{cov}_t (m_{t+1}, s_{t+1})$$

where  $m_{t+1} = \ln\left(\frac{u'(c_{t+1})}{P_{t+1}}\right)$ . If markets are complete, we have  $s_{t+1} - s_t = m_{t+1}^* - m_{t+1}$ , where  $m_{t+1}^* = \ln\left(\frac{u'(c_{t+1}^*)}{P_{t+1}^*}\right)$ . Using this relationship, we can write

(B.14) 
$$i_t^{*m} + E_t s_{t+1} - s_t - i_t^m = r_t$$

where  $r_t = \frac{1}{2} \left( \operatorname{var}_t \left( m_{t+1} \right) - \operatorname{var}_t \left( m_{t+1}^* \right) \right)$ . As noted in the text, we do not insist that  $r_t$  be interpreted as a time-varying risk premium. It may arise for other reasons as well, such as financial market or expectational frictions, or from the presence of noise traders. While we derived (B.14) from (B.6) and (B.8), it is straightforward to check that equations (B.11) and (B.13) imply the same relationship.<sup>47</sup>

<sup>&</sup>lt;sup>47</sup> These relationships are well-known in the literature. See the survey of Engel (2014) for example.

Assume equations (B.4) and (B.5) hold with equality, so that the home agent holds positive amounts of home money and home government bonds. Using (B.5) and (B.6):

(B.15) 
$$\frac{1+i_t}{1+i_t^m} + \frac{\kappa v_M \left(\frac{M_{H,t}}{P_t}, \frac{B_{H,t}}{P_t}, \frac{S_t B_{H,t}^*}{P_t}\right)}{u'(c_t)} = 1.$$

Similarly, using (B.4) and (B.6) gives us:

$$\frac{1}{1+i_t^m} + \frac{v_M\left(\frac{M_{H,t}}{P_t}, \frac{B_{H,t}}{P_t}, \frac{S_t B_{H,t}^*}{P_t}\right)}{u'(c_t)} = 1.$$

Rearranging these two equations, we find:

$$i_t^m - i_t = \frac{\kappa}{1 - \kappa} i_t$$
, which in the text we write as  $i_t^m - i_t = \alpha i_t$ ,  $\alpha > 0$ .

Taking the analogous set of relationships for the foreign country, we arrive at:

$$(i_t^m - i_t) - (i_t^{m^*} - i_t^*) = \alpha (i_t - i_t^*).$$

If we had added a shock to liquidity preferences as in Engel (2016), we would then, using (B.14) arrive exactly at the model given in the text, in which

$$i_t^* + E_t s_{t+1} - s_t - i_t = \eta_t + r_t,$$

where  $\eta_t \equiv (i_t^m - i_t) - (i_t^{m^*} - i_t^*) = \alpha (i_t - i_t^*) + v_t$ .

Note that if the home household holds the foreign government bond, we have:

$$\frac{1+i_t^*}{1+i_t^m} E_t\left(\frac{S_{t+1}}{S_t}\right) + \frac{v_{B^*}\left(\frac{M_{H,t}}{P_t}, \frac{B_{H,t}}{P_t}, \frac{S_t B_{H,t}^*}{P_t}\right)}{u'(c_t)} = 1.$$

Together with equation (B.15), we find:

$$(1+i_{t}^{*})E_{t}\left(\frac{S_{t+1}}{S_{t}}\right) - (1+i_{t}) = (1+i_{t}^{m})\frac{v_{B}\left(\frac{M_{H,t}}{P_{t}}, \frac{B_{H,t}}{P_{t}}, \frac{S_{t}B_{H,t}^{*}}{P_{t}}\right) - v_{B^{*}}\left(\frac{M_{H,t}}{P_{t}}, \frac{B_{H,t}}{P_{t}}, \frac{S_{t}B_{H,t}^{*}}{P_{t}}\right)}{u'(c_{t})}$$

Our model implies that if home households hold both government bonds, the difference in the expected rates of return reflects the difference in the liquidity services that the two bonds provide to home households. If the foreign government bond pays a higher monetary return, it must provide a lower liquidity return to the home household in equilibrium.

## Appendix A2: Data source

Generic data source table

Data	Data source
Spot Exchange rates	Datastream (DS)
1Y Forward rates	Datastream (DS)
1M Forward rates	Datastream (DS)

### Specific data ticker table

All the variables are created by filling the missing value in the order reported. For exchange rates and forward rates, we do a trilateral cross to get the non-US related exchange rates. For example, the AUD per CAD exchange rate is constructed by  $\log(S_{USD/CAD})$ -  $\log(S_{USD/CAD})$ . Germany government yield, debt to GDP and CDS are used for EUR.

### **Appendix A3: Summary statistics**

All the summary statistics of percentage variables scaled by 100 to improve visibility. For example, *i* of 4.06 represents 4.06% annualized interest rate. Interest rates and forward rates reported are with 1-year tenor. AR1 stands for slope coefficient from an AR1 regression and rmse stands for root mean squared errors.
