Abstract

Magnetic microscopy of malarial hemozoin nanocrystals is performed by optically detected magnetic resonance imaging of near-surface diamond nitrogen-vacancy centers. Hemozoin crystals are extracted from *Plasmodium falciparum*-infected human blood cells and studied alongside synthetic hemozoin crystals. The stray magnetic fields produced by individual crystals are imaged at room temperature as a function of the applied field up to 350 mT. More than 100 nanocrystals are analyzed, revealing the distribution of their magnetic properties. Most crystals (96%) exhibit a linear dependence of the stray-field magnitude on the applied field, confirming hemozoin's paramagnetic nature. A volume magnetic susceptibility of 3.4×10^{-4} is inferred with use of a magnetostatic model informed by correlated scanning-electron-microscopy measurements of crystal dimensions. A small fraction of nanoparticles (4/82 for *Plasmodium falciparum*-produced nanoparticles and 1/41 for synthetic nanoparticles) exhibit a saturation behavior consistent with superparamagnetism. L.B., P.K., and (later) V.M.A. conceived the idea for this study in consultation with A.J. P.K. performed initial calculations demonstrating feasibility. I.F., A.J., and V.M.A. designed the experimental plan with input from all authors. J. Smits, P.K., and I.F. wrote and implemented control and automation software. J. Seto extracted the natural hemozoin samples. I.F., A.L., and N.M. built the measurement apparatus, prepared samples, and collected data. I.F. analyzed the data and wrote the initial manuscript draft, under the supervision of V.M.A. All authors discussed the results and contributed to the writing of the manuscript.

L.B., A.J., and V.M.A. are named as coinventors on a related U.S. patent application: 20180203080 A1. A.J. and L.B. are cofounders of ODMR Technologies and have financial interests in the company. The remaining authors declare no competing financial interests.

Plasmodium-infected cells may shed new light on hemozoin formation dynamics and their interaction with antimalarial drugs.

I. INTRODUCTION

Magnetic field sensors based on diamond nitrogen-vacancy (NV) centers have emerged as a powerful platform for detecting nanomagnetism in biological samples [1,2]. With this technique, magnetic fields from magnetotactic bacteria [3], ferritin proteins [4], magnetically labeled cancer cells [5], and neuronal currents [6] have been detected with a remarkable combination of spatial resolution and sensitivity. Diamond magnetic microscopy has even been able to resolve magnetic fields produced by individual nanoparticles exhibiting ferromagnetism and superparamagnetism [7–9]. However, observation of individual paramagnetic nanoparticles at ambient temperature has remained a challenge, owing to their weaker magnetic signatures.

Of particular interest are paramagnetic hemozoin biocrystals that nucleate inside several blood-feeding organisms [10], including the *Plasmodium* species responsible for malaria. Malarial parasites feed on their host's hemoglobin for essential amino acids, while decomposing the iron complexes into highly toxic free radicals. These radicals are subsequently bound into chemically inert elongated crystals (50–1500 nm in size) called “hemozoin” [10–12]. Hemozoin crystals are a biomarker for malaria, and a substantial effort has been devoted to developing diagnostic platforms based on their detection [10,13]. Hemozoin detection is also used in pharmacological studies of malaria [14], since some antimalarial drugs work by altering hemozoin formation [11,12].

Hemozoin crystals have characteristic optical properties, including birefringence [15], linear dichroism [16], and nonlinear dielectric susceptibility [17], that allow their detection without the use of extrinsic labels. They are also paramagnetic due to the presence of unpaired electrons in their Fe^{3+} centers, meaning they are magnetized only in the presence of an external magnetic field. Direct detection of hemozoin's magnetization is intriguing because it gives quantitative information related to crystal size and iron composition.

Several methods of studying hemozoin magnetic signatures have been demonstrated, including magneto-optical rotation [18–20], nuclear-magnetic-resonance relaxometry [21,22], electron paramagnetic resonance [23], and magnetic separation [24]. Direct magnetic detection of hemozoin ensembles has been performed by bulk magnetometry [25–27]. However, detection of stray magnetic fields produced by single hemozoin nanocrystals has not yet been reported, likely due to stringent requirements on sensitivity and spatial resolution.

We hypothesized that diamond magnetic microscopy [3,5,9,28,29] possesses sufficient sensitivity and spatial resolution to image the stray magnetic field produced by individual hemozoin nanocrystals. To test this, we performed room-temperature optically-detected-magnetic-resonance (ODMR) imaging of a NV-doped diamond substrate in contact with either “natural” (*Plasmodium*-produced) or synthetic hemozoin nanocrystals. Spatially resolved maps of the magnetic fields produced by individual hemozoin nanocrystals were

obtained and used to characterize the distribution of their paramagnetic properties. With appropriate modifications, this detection strategy may be used to study the formation dynamics of hemozoin crystals in living *Plasmodium*-infected cells.

II. DETECTION PRINCIPLE

NV centers are spin-1 defects in the diamond lattice. The energy levels and optical excitation and emission path-ways of the NV center are shown in Fig. 1(a). For a magnetic field B_{\parallel} applied along the NV symmetry axis, the $|0\rangle \leftrightarrow |\pm 1\rangle$ spin transition frequencies are $f_{\pm} = D \pm \gamma_{\text{NV}} B_{\parallel}$, where $D = 2.87$ GHz is the zero-field splitting and $\gamma_{\text{NV}} = 28$ GHz/T is the NV gyromagnetic ratio [Fig. 1(b)]. The principle of NV magnetometry is to measure these transition frequencies precisely with ODMR techniques [1,2]. When 532-nm light continuously excites NV centers, the ground-state population is optically polarized into $|0\rangle$ via a nonradiative, spin-selective decay path-way involving intermediate singlet states. Because of the same spin-selective decay mechanism, NV centers excited from $|0\rangle$ emit fluorescence (collected at 650–800 nm) at a higher rate than those originating from $|1_{\pm}\rangle$. Application of a transverse microwave magnetic field mixes the spin populations, resulting in a dip in fluorescence when the microwave frequency matches the spin transition frequencies, f_{\pm} [Fig. 1(c)]. Monitoring of NV fluorescence as the microwave frequency is swept across the resonances reveals f_{\pm} and thus B_{\parallel} .

The minimum detectable magnetic field of a Lorentzian ODMR signal is limited by photoelectron shot noise as [2,30,31]

$$B_{\min} \simeq \frac{4}{3\sqrt{3}} \frac{\Gamma}{\gamma_{\text{NV}} C \sqrt{I_0 t}}, \quad (1)$$

where Γ is the full-width-at-half-maximum (FWHM) linewidth, C is the contrast (the relative difference in ODMR signal on and off resonance), I_0 is the photoelectron detection rate, and t is the measurement time. In room-temperature NV ODMR experiments, the spin projection noise is typically more than one order of magnitude lower than the photoelectron shot noise and is therefore negligible [32–34]. With typical experimental values ($\Gamma = 12$ MHz, $C = 0.02$, $I_0 = 5 \times 10^6$ electrons/s) for a 65×65 nm² pixel, detection Eq. (1) predicts $B_{\min} \simeq 7.4$ μ T for $t = 1$ s. Experimentally, we observe a detection threshold that is within 15% of the photoelectron shot-noise limit [Fig. 1(e)]. The experimentally determined B_{\min} is calculated as the standard deviation of field values in 65×65 nm² pixels in magnetic images lacking visible features. Scaling of the experimental detection threshold to a 390×390 nm² pixel (approximately the diffraction-limited resolution), gives $B_{\min} \simeq 1.4$ μ T threshold for $t = 1$ s. This detection is a factor of six lower than that for 65×65 nm² pixels because I_0 increases by a factor of 36 [Eq. (1)].

This detection threshold is sufficient to image the microtesla fields from hemozoin nanocrystals. In our experimental geometry [Fig. 1(d)], hemozoin crystals are magnetized along the x axis and the B_x component of the magnetic field is detected by diamond magnetic microscopy. In the point-dipole approximation [35], which is valid for crystals

with dimensions smaller than the ~ 390 -nm spatial resolution of our microscope, the magnetic field produced from a single crystal (volume V) is

$$B_x(x, y, z) = \frac{\chi V B_0}{4\pi} \frac{2x^2 - y^2 - z^2}{(x^2 + y^2 + z^2)^{5/2}}, \quad (2)$$

where B_0 is the applied magnetic field and χ is the volume magnetic susceptibility. χ depends on the crystal orientation and purity, and values of $(3.2\text{--}4.6) \times 10^{-4}$ have been reported in the literature [10,18]. For conservative values $\chi = 3.2 \times 10^{-4}$, $V = 100 \times 100 \times 100 \text{ nm}^3$, and NV sensing depth $z = 200 \text{ nm}$, the field produced by a hemozoin nanocrystal in a $B_0 = 350 \text{ mT}$ applied field has a minimum of $B_x = -1.1 \mu\text{T}$ at $x = y = 0$ and maxima of $B_x = 0.2 \mu\text{T}$ at $y = 0$, $x = \pm 245 \text{ nm}$.

To more accurately describe the instrument response, magnetostatic modeling is used to calculate the $B_x(x, y, z)$ field produced by elongated crystals, with dimensions taken from scanning-electron-microscopy (SEM) images. We then integrate B_x over the NV vertical distribution, which is assumed to be uniform from 20 to 220 nm below the diamond surface (Appendix B). Finally, we account for the effect of optical diffraction and image drift by convolution with a two-dimensional Gaussian kernel (“blur”) with 540-nm FWHM. A discussion of model parameters is given in Appendix F.

III. EXPERIMENTAL METHODS

Figure 1(d) depicts the epifluorescence ODMR micro-scope used for diamond magnetic microscopy. The diamond substrate is a [110]-polished, $2 \times 2 \times 0.08 \text{ mm}^3$ type-Ib-diamond substrate grown by high-pressure, high-temperature synthesis. $^4\text{He}^+$ ions were implanted into the substrate [31] at three different energies (5, 15, and 33 keV) to produce a roughly uniform distribution of vacancies in an ~ 200 -nm near-surface layer (see Appendix B). After implantation, the diamond was annealed in a vacuum furnace [36] at $800 \text{ }^\circ\text{C}$ (4 h) and $1100 \text{ }^\circ\text{C}$ (2 h) to produce a near-surface layer of NV centers with a density of $\sim 10 \text{ ppm}$. Microwaves are delivered by copper loops printed on a contacting glass coverslip. A magnetic field, \vec{B}_0 , produced by a pair of permanent magnets, points along one of the in-plane NV axes. A linearly polarized 532-nm laser beam (0.2 W) excites the NV centers over an area of $\sim 40 \times 40 \mu\text{m}^2$, and their fluorescence is imaged onto a scientific CMOS (sCMOS) camera. A detailed description of the apparatus is given in Appendix B.

Magnetic field maps are obtained by performing ODMR imaging of the near-surface NV layer (see Appendix D). Fluorescence images (600 pixels \times 600 pixels, $39 \times 39 \mu\text{m}^2$ field of view, 3-ms exposure time) of the NV layer are recorded at 16 different microwave frequencies around each of the NV ODMR resonances (32 frequencies in total). The sequence is repeated, and the image set is integrated for several minutes to increase the signal-to-noise ratio. The fluorescence-intensity-versus-microwave-frequency data for each pixel are fit by Lorentzian functions to determine the ODMR central frequencies, f_{\pm} . The magnetic field projection along the NV axis is then calculated as $B_{\parallel} \equiv B_0 + B_x = (f_+ - f_-)/$

($2\gamma_{\text{NV}}$). Determining B_{\parallel} in this way eliminates common-mode shifts in f_{\pm} due to temperature-dependent changes in zero-field splitting D [37] and variations in longitudinal strain [33,38]. The external field, B_0 , is subtracted from the image, revealing a map of the stray magnetic fields, B_x , produced by the magnetized nanocrystals.

Figure 2 shows SEM images of the synthetic and natural hemozoin nanocrystals studied here. The synthetically produced hemozoin crystals (t1r1-hz, InvivoGen) have an elongated shape and varied dimensions (50–1500 nm). The natural hemozoin nanocrystals, extracted from human red blood cells cocultured with *Plasmodium falciparum* [24], have similar elongated shapes with slightly larger average dimensions. For diamond magnetic microscopy, hemozoin samples are diluted in water and drop-cast on the diamond surface to yield a relatively nonaggregated surface density with approximately 0.04 nanocrystals/ μm^2 .

IV. RESULTS

Figure 3(a) shows a bright-field transmission image of natural hemozoin crystals dispersed on the diamond sensor's surface. Most of the bright features in the image come from host-cell residue; they do not appear in magnetic images. Results from another region without residue are reported in Appendix 3.

Figure 3(b) displays a modified SEM image of the same region as in Fig. 3(a). We use an image-segmentation procedure (Appendix C) to more clearly visualize the hemozoin crystals. Figure 3(c) shows the corresponding magnetic field map obtained by diamond magnetic microscopy. Of a total of 120 features identified as potential hemozoin nanocrystals in the SEM image, 82 exhibit magnetic features resolved by our technique. Surprisingly, the two magnetic features with the largest magnitude correspond to crystals with dimensions of ~ 200 nm or less in the SEM image. Such anomalously strong features are observed consistently, but infrequently (less than 5% of all magnetic features), in both natural and synthetic hemozoin samples. We tentatively attribute them to superparamagnetism [39], for reasons discussed below.

Five example crystals are labeled n1–n5 in the images in Figs. (b) and 3(c), including one of the aforementioned strongly magnetized nanocrystals (n5). Figure 4(a) shows SEM images of each example crystal; n1–n4 have a typical size and shape for these crystals, whereas n5 is barely visible, with dimensions of < 200 nm. Figure 4(b) shows the corresponding diamond-magnetic-microscopy images taken at $B_0 = 186$ mT. Each crystal exhibits a different field pattern characteristic of its unique size, shape, and orientation.

Figure 4(c) shows the expected magnetic field patterns of each nanocrystal, calculated with the procedure described in Sec. II. Each nanocrystal is modeled as a three-dimensional (3D) ellipsoid with uniform susceptibility and dimensions inferred from the corresponding SEM images. The height of the crystals is assumed to be 200 nm. For n1–n4, the model produces field patterns similar to those observed experimentally. The pattern amplitude is best described with a volume magnetization $M = 50$ A/m, which corresponds to a volume susceptibility $\chi = \mu_0 M / B_0 = 3.4 \times 10^{-4}$, where $\mu_0 = 4\pi \times 10^{-7}$ m T/A is the vacuum permeability. This value of χ is well within the range of literature values for hemozoin

[10,18] and is in good agreement for most crystals, despite a wide variation in their magnetic patterns. This demonstrates that crystal size, shape, and orientation are the primary factors in determining the magnetic pattern behavior. Factors contributing to ~ 25% or less uncertainty in χ are discussed in Appendix F.

For crystal n5, however, the model does a poor job of describing the magnetic behavior. It predicts a field-pattern amplitude more than one order of magnitude lower than the observed value, suggesting n5 is not paramagnetic hemozoin. It is difficult to estimate this particle's magnetization, since it may arise from a small inclusion or an adjacent particle not resolved in the SEM image.

Line cuts of the magnetic field patterns for n1–n5 are shown in Fig. 4(d). The line cuts are obtained by averaging B_x values over six rows (390 nm) in a band along the magnetic feature, as indicated in Figs. 4(b) and 4(c). The line cuts are used to calculate the magnetic pattern amplitude B , determined from the difference in extreme B_x values in the line cuts. The uncertainty in B is approximately $\pm 0.2 \mu\text{T}$, on the basis of the scatter in the B_x values in the line cuts in a magnetic-feature-free region. The amplitudes for n1–n4 differ due to size and shape, but all fall in the range $B = 1.3\text{--}2.9 \mu\text{T}$. However, the amplitude for n5 is much larger, $B = 11.0 \pm 0.2 \mu\text{T}$. The FWHM of this feature is ~400 nm, close to our microscope's diffraction-limited spatial resolution, providing further evidence that it comes from a pointlike particle.

Magnetic images of all nanocrystals shown in Fig. 3 were obtained for six values of the external field: $B_0 = 83, 122, 186, 240, 300,$ and 350 mT. From these images, we identify 82 individual magnetized crystals and calculate B as a function of B_0 for each of them. The $B(B_0)$ curves for all 82 crystals are provided in Fig. 13. Figure 4(e) shows the curves of nanocrystals n1–n5. A linear dependence is found for n1–n4 and is characteristic of a paramagnetic response. In total, 78 of 82 natural hemozoin crystals show a similar linear behavior, with a slope in the range $d B/dB_0 = 4\text{--}16 \mu\text{T}/\text{T}$.

The remaining four nanoparticles from the natural hemozoin sample exhibit a saturation behavior, as seen for n5. These curves are fit with a Langevin function of the form $B(B_0) = a[\coth(bB_0) - 1/(bB_0)]$, where a and b are fit parameters. For n5, $a = 13.3 \pm 0.7 \mu\text{T}$ and $b = 0.017 \pm 0.002 \text{ mT}^{-1}$. This model is commonly used to describe superparamagnetic nanoparticles in the limit that the thermal energy exceeds the magnetic anisotropy energy [40]. The large magnetization and saturation behavior observed in these small nanoparticles is consistent with recent reports of superparamagnetism in hemozoin samples [39,41]. However, only a small fraction (~ 5% or less) of the nanoparticles exhibit such behavior. This may explain why superparamagnetic behavior was not observed in previous ensemble studies with unrefined samples [18,22,25]. The atomic structure of these outlier nanoparticles remains a topic for future work.

A histogram of B for all 78 paramagnetic nanocrystals at $B_0 = 350$ mT is shown in Fig. 4(f). The distribution is characterized by a mean amplitude of $2.9 \mu\text{T}$, a median of $2.6 \mu\text{T}$, and a standard deviation of $1.6 \mu\text{T}$. Figure 4(f) plots the best-fit slopes, $d B/dB_0$, as a function of crystal area, as determined from SEM images. The slopes increase in a roughly monotonic

fashion before saturating when the crystal dimensions exceed the spatial resolution of the microscope. This behavior is expected for crystals with uniform susceptibility. For crystal volumes much smaller than the sensing voxel, $V \ll V_{\text{sense}} \approx 0.4 \times 0.4 \times 0.2 \mu\text{m}^3$, Eq. (2) predicts $d B/dB_0 \propto \chi V$, while for $V \gg V_{\text{sense}}$ we expect $d B/dB_0 \propto \chi$ independent of crystal dimensions.

We have also measured the magnetic properties of synthetic hemozoin crystals manufactured by InvivoGen. These nanocrystals are commonly used as a model for natural hemozoin, owing to their ease of procurement and nearly identical crystal morphology and chemical structure [42,43]. Previous studies reported similarities in the ensemble magnetic properties of synthetic and *Plasmodium falciparum*-extracted hemozoin [44]; however, here we compare the distribution of their magnetic properties at the single-nanocrystal level.

Figure 5(a) shows a confocal reflection image of dried synthetic hemozoin crystals dispersed on the diamond substrate. Of a total of 46 dark features identified as potentially being hemozoin, 41 produce magnetic features in the diamond-magnetic-microscopy images [Fig. 5(b)]. As with natural hemozoin, $B(B_0)$ curves are generated by monitoring these features in magnetic images taken at six different applied fields. The $B(B_0)$ curves for all 41 nanocrystals are displayed in Fig. 14. One nanocrystal exhibits a Langevin saturation, suggesting superparamagnetic behavior, while the remaining 40 crystals exhibit a linear dependence. Figure 5(c) shows the $B(B_0)$ curves for three example nanocrystals exhibiting linear behavior, labeled s1–s3 in Fig. 5(b). Magnetostatic modeling [Fig. 10(d)] of these three nanocrystals shows good agreement with the experimental images with $\chi = 3.4 \times 10^{-4}$. This is the same value as found for natural hemozoin [Figs. 4(c) and 4(d)], indicating the natural and synthetic crystals have similar magnetic properties.

Figure 5(d) shows histograms of the fitted slopes, $d B/dB_0$, for all 40 paramagnetic synthetic crystals and all 78 paramagnetic natural crystals. The synthetic nanocrystals have a slightly smaller slope (mean 5.5, median 4.3 $\mu\text{T}/\text{T}$) than natural hemozoin (mean 8.1, median 7.2 $\mu\text{T}/\text{T}$), while the standard deviation is similar (6.2 and 8.0 $\mu\text{T}/\text{T}$, respectively). This is likely due to a small difference in their size distributions (see Appendix C and Fig. 8).

V. OUTLOOK AND CONCLUSION

Our results demonstrate the capability of diamond magnetic microscopy to simultaneously measure the magnetic properties of numerous individual biocrystals. Whereas bulk measurements yield ensemble-average properties, diamond magnetic microscopy can measure the distribution of nanocrystal susceptibilities, extract information about each crystal's dimensions and orientation, and differentiate paramagnetic hemozoin from superparamagnetic nanoparticles. This brings up the intriguing possibility of using this platform to monitor the formation dynamics of individual hemozoin nanocrystals in living cells without the use of extrinsic contrast agents.

To assess the feasibility of performing magnetic imaging of hemozoin inside cells, we estimate a typical hemozoin crystal volume is $V = 0.04 \mu\text{m}^3$, on the basis of the median area

found from SEM images ($0.2 \mu\text{m}^2$) and an assumed thickness of $0.2 \mu\text{m}$. We assume the hemozoin crystal forms in a digestive vacuole within a *Plasmodium*-infected red blood cell (typical thickness $2 \mu\text{m}$ [13]) such that it is located $2 \mu\text{m}$ from the diamond surface. Such a crystal with susceptibility $\chi = 3.4 \times 10^{-4}$ under an applied field $B_0 = 350 \text{ mT}$ would produce a magnetic pattern amplitude at the diamond surface ($z = 2 \mu\text{m}$) of $B = 0.057 \mu\text{T}$ [Eq. (2)]. This field shift would be detectable with a signal-to-noise ratio of one after ~ 10 min of averaging using the present diamond sensor with $390 \times 390 \text{ nm}^2$ detection pixels (see Sec. II). However, the 200-nm NV layer currently used is optimized for negligible diamond-hemozoin separation. If the separation is $\sim 2 \mu\text{m}$, an NV layer of $1 \mu\text{m}$ would be more optimal, leading to a signal-to-noise ratio of one after approximately 2 min. If a higher magnetic field is used (already realized for nanoscale NV magnetometry [45,46]), a signal-to-noise ratio of one should be obtained for $B_0 = 3 \text{ T}$ after $\sim 1.6 \text{ s}$ of signal averaging.

This sensitivity would be sufficient to monitor the formation dynamics [47] of individual hemozoin nanocrystals on minute-to-hour timescales. It could enable monitoring of crystal position and orientation throughout the parasite life cycle under different conditions, including the influence of antimalarial drugs. However, the movement of red blood cells would need to be constrained such that crystals remain close to the diamond surface. This may be accomplished by promotion of cell adhesion [48] or sedimentation [49], confinement of cells within microstructures [36,50], and/or increase of the viscosity of the surrounding medium [51–53]. If the platform is simplified and miniaturized, it may also find application as a label-free malaria diagnostic tool with sensitivity rivaling the current staining or microscopy standard [18]. Our platform can also be used to study paramagnetic substances other than hemozoin. Figure 11 shows diamond-magnetic-microscopy images of the pharmacological agent hemin.

In summary, we use diamond magnetic micro-scopy to characterize the distribution of magnetic properties of synthetic and natural hemozoin samples at the individual nanocrystal level. More than 95% of the nanocrystals exhibit paramagnetic behavior, with magnetic field patterns well described by a magnetostatic model using a volume susceptibility $\chi = 3.4 \times 10^{-4}$. Five of the 123 nanocrystals studied exhibit anomalously large magnetization that saturates at fields above approximately 0.1 T, suggesting superparamagnetism. Further work is needed to determine the composition and structure of these outlier nanoparticles. With improvements in the experimental setup, diamond magnetic microscopy should be capable of imaging hemozoin formation dynamics in living cells, with implications for malaria diagnosis and drug development.

APPENDIX A: HEMOZOIN

Hemozoin crystals consist of dimers of α -hematin molecules each containing an iron center. Figure 2 shows the molecular structure of a dimer, constructed with the Avogadro open-source molecular builder and visualization tool. The central iron of the first α -hematin is bonded to the oxygen of the carboxylate side chain of the second α -hematin. The dimers are joined by hydrogen bonds to form a triclinic crystal [47]. These crystals are alternatively called “hemozoin” or “ β -hematin.” Throughout this paper, we use the term “hemozoin” to refer to crystals produced both naturally (through biocrystallization inside living organisms) and synthetically.

The organisms that produce hemozoin crystals include the various *Plasmodium* species, the parasitic worm *Schistosoma mansoni*, the avian protozoan parasite *Hemoproteus columbae*, and the kissing bug *Rhodnius prolixus* [47]. In humans, hemozoin plays an important role in the pathological mechanism of the *Plasmodium* parasites responsible for malaria, a disease that has devastating effects in tropical and subtropical regions [10].

During their life cycle, malarial protozoans feed on host-cell hemoglobin by decomposing it inside digestive vacuoles into amino acids and toxic α -hematin radicals [10–13]. The iron radicals are then bound, inside the same vacuoles, into inert hemozoin crystals and released into the host blood during erythrocyte disintegration.

The suppression (or alteration) of hemozoin formation inside *Plasmodium* parasites is considered a key action of widely used antimalarial drugs, such as quinine and chloroquine [11,12]. Quinine has been successfully used for more than 300 years to treat malaria by suppressing hemozoin crystallization [12]. Chloroquine has been widely used since the 20th century and is thought to invoke a similar response in hemozoin formation [11,12]. The regular use of these drugs led to the selection of resistant forms of *Plasmodium* parasites, which carry genes responsible for preventing the drugs from entering digestive vacuoles [11,12].

The motivation for the present study was to establish diamond magnetic microscopy as an effective tool for fast, quantitative, noninvasive characterization of individual hemozoin nanocrystals. Translation of this technique to the study of hemozoin formation in living protozoans could be used to elucidate the interaction between hemozoin formation, the host immune system, and antimalarial drugs. This line of inquiry may even lead to the establishment of a bank of effective antimalarial drugs able to counteract the highly adaptive parasites.

APPENDIX B: EXPERIMENTAL DETAILS

The diamond substrate used in this work is a [110]-polished, $2 \times 2 \times 0.08$ mm³ type-Ib-diamond grown by high-pressure, substrate high-temperature synthesis. The diamond was acquired from Delaware Diamond Knives Inc. and had an initial nitrogen concentration of ~ 100 ppm. $^4\text{He}^+$ ions were implanted in the substrate by CuttingEdge Ions LLC [31] at three different energies (5, 15, and 33 keV) to produce a roughly uniform distribution of vacancies in an ~ 200 -nm near-surface layer. Vacancy distribution depth profiles are estimated by

Stopping and Range of Ions in Matter (SRIM) Monte Carlo simulation [Fig. 6(a)]. The diamond substrates are modeled as a pure carbon layer with density of 3.52 g/cm^3 and atom-displacement threshold energy of 37.5 eV. The lattice-damage threshold and surface-damage threshold are set to 7.35 and 7.5 eV, respectively. SRIM simulations do not take into account crystallographic effects such as ion channeling, and therefore could lead to underestimation of the vacancy-layer depth, but are sufficiently accurate for our purposes. Our SRIM simulations predict a modal depth of approximately 24 nm (the depth where the vacancy density is greatest) for 5-keV $^4\text{He}^+$ -ion implantation, approximately 72 nm for 15 keV, and approximately 130 nm for 33 keV. The diamond substrate was implanted with helium ion doses of 4×10^{12} , 2×10^{12} , and $2 \times 10^{12} \text{ He/cm}^2$ for implantation energies of 5, 15, and 33 keV, respectively. SRIM simulations [Fig. 6(a)], indicate this produces a vacancy density of approximately 50 ppm with approximately 30% or less variation throughout the layer. After implantation, the diamond was annealed in a vacuum furnace at 800 and 1100 °C [Fig. 6(b)]. This process resulted in an ~ 200 -nm near-surface layer of NV centers with a density of approximately 10 ppm, as determined by the fluorescence intensity [30]. The largest source of uncertainty in the final NV-layer distribution is the extent of vacancy diffusion during annealing. Previous studies [54] predicted tens of nanometers of diffusion during annealing of type-Ib diamonds grown by high-pressure, high-temperature synthesis under similar conditions. We thus expect a slight broadening of the vacancy distribution in Fig. 6(a) to approximately 200 nm after annealing.

To magnetize nanocrystals, we use the static magnetic field created by a pair of permanent magnets [Fig. 1(d)]. The magnetic field is aligned to the [110]-polished diamond surface such that B_0 is parallel to one of the two possible in-plane NV symmetry axes. Microwave fields are delivered by two copper loops (each addressing a different spin transition) printed on a glass coverslip. The loops are positioned with respect to the diamond to maximize the microwave-field components orthogonal to the NV axis. The microwaves are generated by a Stanford Research Systems SG384 frequency generator with two outputs for the first and second harmonics. The frequency of the generator is swept by sending a ramp function to the generator's analog frequency-modulation input. For $B_0 > 186 \text{ mT}$, additional frequency doublers (Mini-Circuits ZX90-2-24-S+ and ZX90-2-36-S+) are used on both harmonic outputs to access higher microwave frequencies. The microwaves for each transition are amplified separately by Mini-Circuits amplifiers: ZHL-16W-43-S+ (for microwave frequencies below 4 GHz), ZVE-3W-83+ (for 4–8 GHz), and ZVE-3W-183+ (for more than 8 GHz). The output of the amplifiers is subsequently routed to the coverslip-printed loops.

To produce NV fluorescence, $\sim 0.2 \text{ W}$ of 532-nm light from a Lighthouse Photonics Sprout-G-10W laser is used in a homebuilt inverted epifluorescence microscope [Fig. 1(d)]. We use an oil-immersion objective with a numerical aperture of 1.3, but an air gap between the coverslip and diamond reduces the diffraction-limited spatial resolution to $\sim 390 \text{ nm}$. The laser light is focused to the lateral periphery of the objective's back focal plane to produce an illumination region of $\sim 40 \times 40 \mu\text{m}^2$ on the diamond's top surface (the surface in contact with the dry hemozoin). By excitation in this way, the laser beam enters the bottom of the transparent diamond substrate at a steep angle, leading to substantial internal reflection from the top diamond-air interface. This is helpful in maximizing NV excitation intensity, while minimizing the intensity incident on hemozoin samples. We find no evidence of

photodamage on hemozoin samples even after studying them under intense, continuous illumination for several days. For sensitive samples, a light-shield layer, ~ 50 nm thick, can be used to block all light from interacting with the sample [55]. For example, coating the face of the diamond that interfaces with the sample with a metal layer (e.g., Ag or Al) of ~ 25 nm would result in reflection of all light, particularly when combined with excitation at an angle exceeding the total-internal-reflection angle. Adding an additional dielectric layer of ~ 25 nm on top of the metal (e.g., SiN, SiO₂, or Al₂O₃) would further prevent any evanescent optical field from interacting with the sample even if cells are adhered to the top of the sensor.

The microscope is operated on a standard vibration-isolation optical table in a climate-controlled laboratory environment. The fluorescence is spectrally filtered by a dichroic mirror and a Semrock BrightLine 731/137 nm band-pass filter, focused by a 200-mm-focal-length achromatic lens (Thorlabs ITL200), and detected by a Hamamatsu Orca v2 sCMOS sensor. By alternation of a flip mirror, the fluorescence could also be detected by a Thorlabs APD410A avalanche photodiode connected to a Yokogawa DL9040 oscilloscope for faster tuning and alignment. The same microscope configuration is used to obtain bright-field transmission images by collecting white light transmitted through the analyte and diamond.

A LabVIEW program is used to control the experiment. A software command triggers the camera to initiate a burst of sixteen 3-ms frames in rolling-shutter mode. Just before the first frame, the camera provides a precisely timed transistor–transistor logic (TTL) pulse that is used to trigger a sequence generated by a National Instruments multifunction data-acquisition module. The data-acquisition module provides an analog ramp function that is used to sweep the microwave-generator frequency via its analog frequency-modulation input. Sixteen frames are acquired for each microwave sweep. After each sweep, the microwave generator is reconfigured via a general-purpose-interface-bus command to alternate between first and second harmonics to alternately address f_+ or f_- transitions. Frame acquisition and real-time Camera image processing are synchronized via the LabVIEW interface. The image-processing procedure is described in detail in Appendix D.

APPENDIX C: HEMOZOIN PREPARATION AND CHARACTERIZATION

Synthetic hemozoin crystals were purchased from InvivoGen™ (trl-hz) and natural hemozoin crystals were obtained from human red blood cells co-cultured with *Plasmodium falciparum* parasites. The hemozoin samples were centrifuged several times (5 min at 6000 rpm) in deionized water to wash out salts and cell residues. They were subsequently sonicated to minimize aggregation, and finally homogeneously dispersed on the diamond surface by dropcasting the hemozoin suspension and wicking away the water until it had dried.

The shape, size, and orientation of the hemozoin crystals were investigated by SEM (UNM Center for High Technology Materials and DOE Center for Integrated Nanotechnologies) and confocal reflectance microscopy (UNM Comprehensive Cancer Center Fluorescence Microscopy Shared Resource). An SEM image for the synthetic hemozoin sample reported in the main text was not obtained due to the sample's early destruction. However confocal

reflectance images (405 nm excitation) were obtained, which offer a spatial resolution of ~ 225 nm.

Figure 7(a) shows the raw SEM image of the natural hemozoin sample studied in the main text. The faint slanted-line pattern is due to imperfections in the diamond polishing. Although the raw SEM images are of high-enough quality to identify and measure hemozoin crystals, there is some background due to cell residue. We thus post-process the raw SEM image to enhance hemozoin visibility in Fig. 3(b). The hemozoin crystals are selected with the free selection tool in the graphics editor GIMP, and a mask is created from the selection [Fig. 7(b)]. The mask is used to colorize the selected crystals, and the inverted mask is used to diminish the contrast of the background.

We use another set of 78 synthetic hemozoin crystals [Fig. 8(a)] to characterize the distribution of sizes in the synthetic hemozoin sample. Figure 8(b) shows a histogram of the nanocrystal areas for natural and synthetic hemozoin crystals. The mean area is $0.16 \mu\text{m}^2$ for synthetic hemozoin and $0.20 \mu\text{m}^2$ for natural hemozoin. The slightly larger size of natural crystals is in agreement with the slightly larger magnetic fields produced by those crystals, as seen in Fig. 5(d).

In the limit that the crystal dimensions are smaller than the magnetic image resolution, we expect the relationship between χ , the mean crystal area (\bar{A}), and the mean magnetization slope ($\overline{d\Delta B/dB_0}$) is $\chi \propto \overline{d\Delta B/dB_0} \bar{A}^{3/2}$, where we assume that the mean crystal volume is proportional to $\bar{A}^{3/2}$. Using values from Figs. 5(d) and 8(b), we find $\overline{d\Delta B/dB_0} \bar{A}^{3/2}$ for synthetic crystals and $90 (\mu\text{T/T})/\mu\text{m}^{3/2}$ for natural crystals. These nearly identical values support our claim that χ is approximately the same for both populations and that the slightly larger size of natural crystals accounts for their slightly larger magnetic fields.

In Sec. IV, we report that 82 of 120 features identified in the natural-hemozoin SEM images produce observable magnetic features. We also report that 41 of 46 features observed in synthetic hemozoin reflectance images produce observable magnetic features. There are two possible explanations for why some particles do not produce magnetic features: (i) the particles are paramagnetic but we cannot observe their magnetization with the available signal-to-noise ratio or (ii) the particles are actually diamagnetic and we have misidentified them as hemozoin crystals from the SEM (or reflectance) images. Considering many of these features had an area comparable to, or larger than, the mean crystal area, the first explanation would require that the magnetically inactive crystals have anomalously small volume susceptibility. This is inconsistent with the monolithic hemozoin-crystal structure, which would predict much smaller variations in χ . We therefore conclude that the second explanation is more likely.

APPENDIX D: DIAMOND-MAGNETIC-MICROSCOPY IMAGE PROCESSING

The principle of our image-processing procedure is shown in Fig. 9. While the microwave frequency is swept in a range of ~ 12 MHz about each ODMR transition, a set of 32 arrays of fluorescence images are acquired from the sCMOS sensor and accumulated for signal averaging. Each of the images comprises 600 pixels 600 pixels. Each pixel corresponds to an

area of $65 \times 65 \text{ nm}^2$ in the sample plane [Fig. 9(d)]. The images are arranged in two image stacks with dimensions of $16 \times 600 \times 600$, where the first dimension is arranged by microwave frequency. By fitting Lorentzian functions along the microwave-frequency dimension, we produce two 600×600 images corresponding to each ODMR central frequency [Figs. 9(b) and 9(e)].

The ODMR central frequency of a particular pixel probed in a particular pixel of the sensor contains information about the local magnetic field, $B_0 + B_x$. However, other factors, such as strain or temperature [37], can also produce frequency shifts. Fortunately, the difference of the two ODMR frequencies gives a pure measure of the magnetic field, $f_+ - f_- = 2\gamma_{\text{NV}}(B_0 + B_x)$. Subtraction of the contribution from B_0 gives the final magnetic images as in Figs. 9(c) and 9(f). The horizontally varying pattern in Fig. 9(e) is actually varying along columns of the sCMOS sensor (the images are rotated by 90° in our setup). This is an artifact of using the sCMOS sensor's rolling-shutter mode. The sCMOS camera has two sensors, and the read-out from each sensor starts from the center rows and moves out to the edges of the sCMOS chip. The total read-out time is $\sim 3 \text{ ms}$, which is approximately the same as the exposure time. This means that rows in the center see a microwave frequency different from that seen by the rows at the edges. The difference is approximately the sweep range divided by the number of microwave points, $12 \text{ MHz}/16 = 0.75 \text{ MHz}$. To eliminate this artifact, we scan the microwave frequencies across both ODMRs in the same direction for $B_0 < 102.5 \text{ mT}$ (f_+ and f_- are both positive), whereas for $B_0 > 102.5 \text{ mT}$ (f_+ and f_- have opposite signs) we scan the microwave frequencies in opposite directions. This scanning and subtraction procedure is effective in removing this artifact [Fig. 9(f)].

We use 16 frequencies per ODMR peak, as we find that near-shot-noise-limited performance can be realized in this manner without introducing artifacts. This leads to a maximum magnetic image acquisition rate of $\sim 10 \text{ Hz}$. While we have performed Lorentzian fitting off-line, if one has to implement this postprocessing procedure in real time, the image rate may be further reduced. However, in principle, only two frequencies per resonance are necessary, and in this manner the ODMR positions could be determined algebraically without Lorentzian fitting. This would allow magnetic image refresh rates of $\sim 100 \text{ Hz}$, enabling video recording of fast dynamics.

APPENDIX E: AUXILIARY RESULTS

1. Magnetostatic modeling of s1–s3

Three individual crystals, labeled s1–s3 in the images in Figs. 5(b) and 5(c), are addressed in detail in Fig. 10. Figure 10(a) shows confocal reflection images of each crystal. Figure 10(b) shows the corresponding diamond-magnetic-microscopy images taken at $B_0 = 186 \text{ mT}$. As with the natural hemozoin sample shown in Figs. 4(a)–4(c), each synthetic crystal exhibits a different field pattern characteristic of its unique size, shape, and orientation.

Figure 10(c) shows the expected magnetic field patterns of each nanocrystal, calculated using the procedure described in Sec. II. Each nanocrystal is modeled as a 3D ellipsoid with uniform susceptibility and dimensions roughly estimated from the corresponding confocal

reflection images. The height of the crystals is assumed to be 200 nm. For all crystals, the model produces similar field patterns to those observed experimentally. The pattern amplitude is best described using a susceptibility of $\chi = 3.4 \times 10^{-4}$, which is the same as the value of χ used for natural hemozoin crystals (Sec. IV).

Line cuts of the magnetic field patterns for s1–s3 are shown in Fig. 10(d). The line cuts are obtained by averaging B_x values over six rows (390 nm) in a band along the magnetic feature, as indicated in Figs. 10(b) and 10(c). The line cuts are used to calculate the magnetic pattern amplitudes B at each value of B_0 . The results of this analysis are displayed in Figs. 5(c) and 5(d) and 14.

2. Diamond magnetic microscopy of hemin

Our diamond magnetic microscope is capable of imaging paramagnetic substances other than hemozoin. Of possible interest are hemin microcrystals, which are used as a pharmacological agent for treating porphyria [56]. Hemin crystals have magnetic susceptibility similar to that of hemozoin but are much larger (up to 30 μm). They thus serve as a convenient test sample for imaging paramagnetism.

3. Natural hemozoin in a second field of view

In addition to the hemozoin samples discussed in Sec. IV, we have also studied natural hemozoin crystals in a second region of the diamond substrate. Figures 12(a)–12(c) show, respectively, bright-field transmission, SEM, and diamond-magnetic-microscopy images in this second field of view. The hemozoin density is sparser in this region (only 12 crystals are identified) and less cell residue is present. Figure 12(d) shows the $B(B_0)$ curves for each of the 12 crystals, and Fig. 12(e) shows the histogram of the fitted slopes. The distribution is similar to that for natural hemozoin shown in Fig. 5(d). Figure 12(f) shows a magnified view of the SEM and magnetic images containing four crystals.

4. Complete field-dependent magnetization data set for samples studied in Sec. IV

Figure 13 shows $B(B_0)$ curves for all 82 observed magnetic features in the natural hemozoin sample. The paramagnetic crystals are labeled with yellow numbers, while particles exhibiting superparamagneticlike behavior are labeled with red numbers. The corresponding magnetic features are labeled with numbers on the wide-field magnetic image (taken at $B_0 = 350$ mT).

Figure 14 shows $B(B_0)$ curves for the 41 magnetic features observed in the synthetic hemozoin sample reported in Sec. IV. The particle exhibiting superparamagnetic behavior is labeled with a red number. The corresponding magnetic features are labeled with numbers on the wide-field magnetic image (taken at $B_0 = 350$ mT).

Figure 11(a) shows a bright-field transmission image of hemin crystals dispersed on a diamond substrate. Figure 11(b) shows the corresponding diamond magnetic image. The magnetic pattern of these crystals appears different from the field patterns presented

elsewhere in this paper. This is because we have used a different diamond substrate (with a 1.7- μm -thick NV layer) that is polished with [100] surfaces. All four NV axes in this substrate are directed at 55° from the surface normal, and the magnetic field is applied along one of these NV axes. This geometry leads to more asymmetric patterns than the in-plane field geometry used elsewhere. The pattern amplitudes are consistent with a magnetic susceptibility $\chi \approx 3 \cdot 10^{-4}$, similar to that of hemozoin. Some smaller particles shown on Fig. 11 are hemozoin crystals measured along with hemin crystals.

APPENDIX F: UNCERTAINTY IN SUSCEPTIBILITY

For both natural and synthetic hemozoin, we estimate a relative uncertainty in χ of $\sim 25\%$ or less due to imperfect assumptions on NV-layer distribution, image blur, and hemozoin crystal dimensions and shape (see Fig. 15). The image blur is incorporated by convolving the magnetic image with a two-dimensional Gaussian kernel. Some of these assumptions are conflated; for example, image blur and crystal height both contribute to the width of the line cuts seen in Figs. 4(d) and 10(d). We find the best agreement when using a blur with a FWHM of 540 nm and a crystal height of 200 nm. However, we have observe some magnetic features with a FWHM of 400 nm, such as n5 in Fig. 4(d), which is closer to the expected diffraction-limited resolution of our microscope (~ 390 nm). This suggests either the image blur is spatially varying (due to imaging aberrations) or the extra modeled blur is compensating imperfections in another assumption, such as crystal height. We find that reducing the image blur by 15% [Fig. 15(b)] leads to a best-fit estimate of $\chi = 2.7 \times 10^{-4}$, which is 21% smaller than the estimate made in Sec.IV. However, the overall agreement with use of those parameters is slightly worse than for the assumptions of 540-nm blur and $\chi = 3.4 \times 10^{-4}$ made in Sec. IV. By comparing the best-fit values of χ under various reasonable perturbations to the model, we arrive at an uncertainty in χ of $\sim 25\%$ or less.

Another source of systematic uncertainty is that we treat χ as an isotropic quantity. Two factors suggest χ is actually anisotropic [18]: (i) the crystals are elongated, and therefore may be more susceptible to magnetize along their long axes, and (ii) the iron centers in hematin dimers have C_{4v} symmetry [Fig. 2(c)], which is largely preserved after crystal formation. The latter suggests a hard axis and an easy plane, whereas the former suggests all three components of magnetization may be different. Butykai *et al.* [18] made the hard-axis and easy-plane assumption and found a magnetic anisotropy $M_{\text{hard axis}}/M_{\text{easy plane}}$ of 1.16 ± 0.03 at room temperature. We have not incorporated magnetic anisotropy in our model because we have not directly measured it and we do not have information about crystal orientation. However, the variation in χ due to anisotropy is smaller than the estimated uncertainty due to imperfect model assumptions. Nonetheless, it may be a contributing factor to the slight disagreement for some crystals, such as n2 [see Fig. 4(d)]. None of these uncertainties come close to being large enough to explain the behavior of n5 or the other presumed superparamagnetic nanoparticles.

APPENDIX G: SUPERPARAMAGNETISM

Several points are made in Sec. IV that support the argument that five outlier nanoparticles (including n5) are superparamagnetic. Here we outline four more pieces of evidence supporting this argument:

- a. The nanoparticles are small. For two of the features we do not see anything in the SEM images at the locations of the magnetic features. The other features do have small corresponding particles in their SEM (or confocal reflectance) images, but we cannot be sure they are responsible for the magnetic features.
- b. All five particles have zero coercivity; that is, $B(0) = 0$. Thus, they are unlikely to be ferromagnetic.
- c. The magnetic patterns of these particles are always aligned in the same way as the features from the linear paramagnetic crystals. This further decreases the likelihood these particles are ferromagnetic since they appear to be magnetized by the applied field even at fields below 0.1 T.
- d. The magnetizing field (the B_0 field needed to magnetize the particles to half their maximum saturation magnetization) is ~ 0.1 T. This is a reasonable value for superparamagnetic particles [61].

APPENDIX H: COMPARISON WITH OTHER IMAGING METHODS

Several techniques capable of label-free imaging of individual hemozoin crystals are compared in Table I. Optical methods such as absorption microscopy, polarization microscopy, and differential interference microscopy use weak optical fields and are able to register high-contrast images of hemozoin at fast frame rates (~ 100 Hz). Resonance Raman microscopy and third-harmonic-generation imaging use more-invasive focused laser beams and require slower scanning, but are capable of visualizing hemozoin with a high degree of specificity. In contrast, diamond magnetic microscopy does not require penetration of light into the hemozoin sample [55] and is the only method capable of registering quantitative magnetic images of individual hemozoin crystals. The frame rate of our method of ~ 1 Hz is slower than that of the weak optical probe methods but comparable to that of third-harmonic-generation imaging and resonance Raman microscopy.

The perturbative nature of diamond magnetic microscopy lies in the application of weak microwave pulses and a large dc-bias magnetic field. The microwave field could, in principle, lead to heating of the sample. We typically use a low-enough microwave power that the diamond temperature increases by ~ 2 °C or less, as measured by the shift in NV ODMR [37]. Considering diamond's excellent thermal properties, we can expect that the samples will undergo an even-smaller temperature change. Diamond magnetic microscopy has already been successfully applied to the study of living cells [3,5,62,63]. It is not known whether the introduction of a large bias field may impact hemozoin formation processes in red blood cells. If this is found to be invasive, a time-lapse approach may be required where the field is off for long periods followed by short measurement intervals.

**FIG. 1.**

Diamond magnetic microscopy. (a) NV energy-level diagram depicting magnetic sublevels ($|0\rangle$, $|\pm 1\rangle$), optical (green arrow), fluorescence (red arrows), and nonradiative (gray arrows) pathways. Gray arrows excitation show spin-selective intersystem crossing leading to polarization into the $|0\rangle$ ground-state sublevel. (b) Energy splitting of the ground-state sublevels in an external magnetic field applied along the NV axis. Blue arrows indicate the f_{\pm} microwave transitions. (c) Example of an ODMR spectrum. From the separation between peaks, the projection of the local magnetic field along the NV axis is inferred. (d) Epifluorescence ODMR microscope used for magnetic imaging. Dry hemozoin crystals are placed on top of a diamond substrate with an $\sim 0.2\text{-}\mu\text{m}$ top layer doped with NV centers. (e) Experimental and photoelectron-shot-noise-limited detection threshold for $65 \times 65 \text{ nm}^2$ detection pixels versus averaging time. The experimental data are fit to the function $B_{\min} = a/\sqrt{t}$ with $a = 8.4 \pm 0.1 \mu\text{T s}^{1/2}$

FIG. 2. Hemozoin nanocrystals. (a) SEM image of synthetic hemozoin nanocrystals on a diamond substrate. (b) SEM image of natural hemozoin nanocrystals extracted from human red blood cells cocultured with *Plasmodium falciparum*, on a diamond substrate. (c) Molecular structure of a hemozoin dimer, which can form hemozoin crystals when joined together by hydrogen bonds. The molecular structure is expected to be the same for natural and synthetic hemozoin crystals.

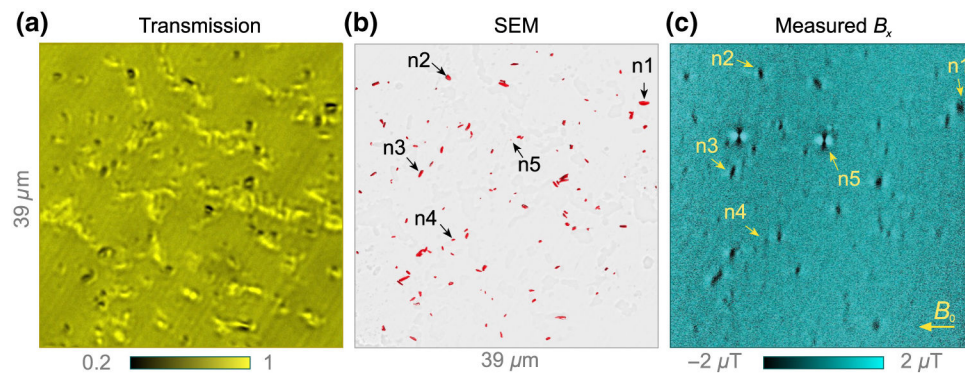

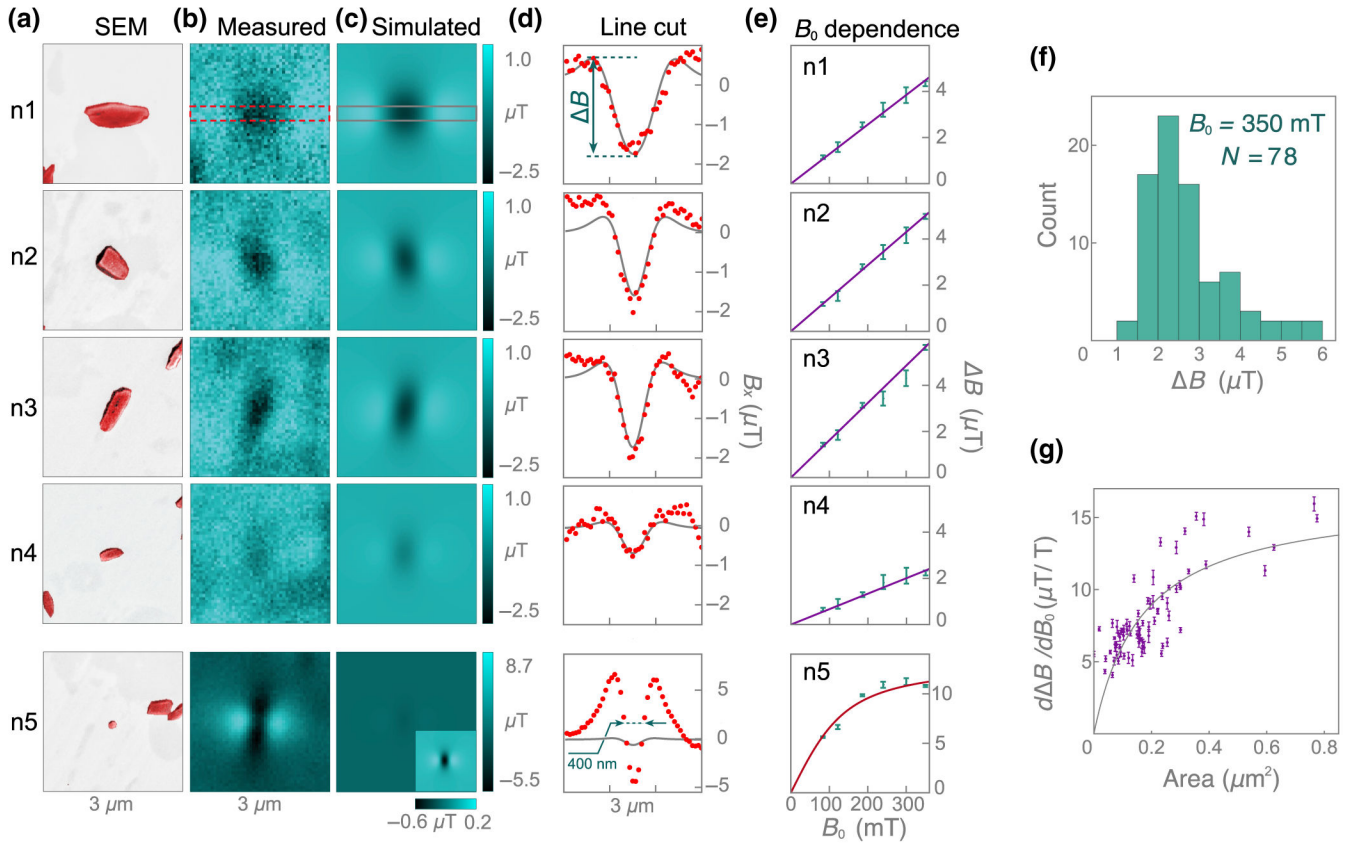

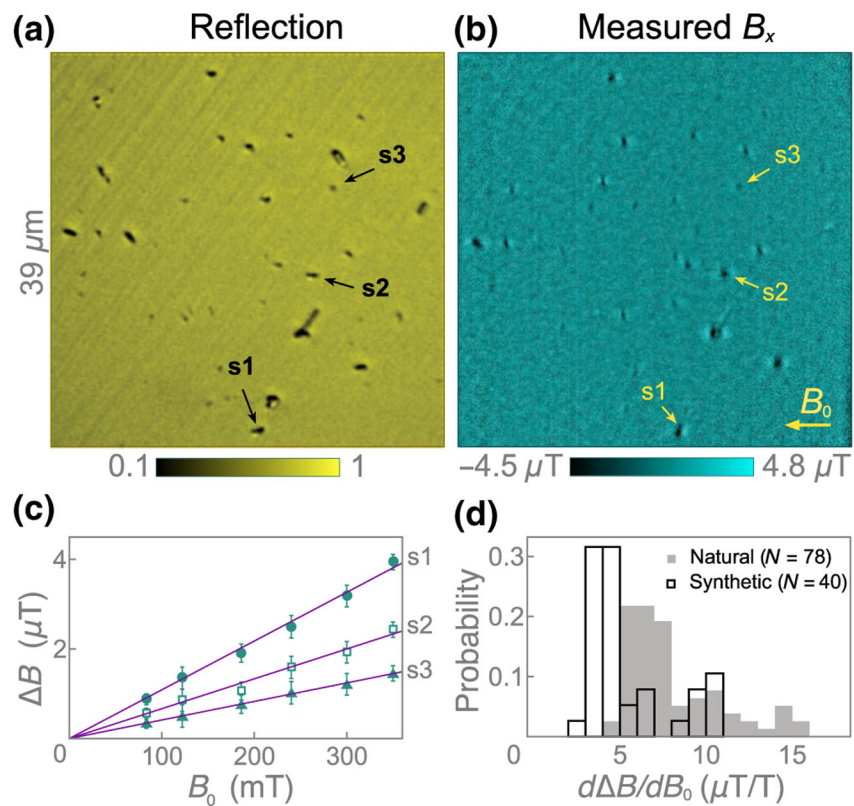

FIG. 3. Natural hemozoin. (a) Bright-field transmission image of natural hemozoin crystals dispersed on a diamond substrate. The scale bar is the relative transmission. (b) SEM image of the same nanocrystals. To enhance hemozoin visibility, the SEM image is modified by a segmentation procedure, depicted in Fig. 7. (c) Diamond-magnetic-microscopy image for applied field $B_0 = 350$ mT. Nanocrystals labeled n1–n5 are studied in detail in Figs. 4(a)–4(e).

**FIG. 4.**

Magnetic imaging of individual natural hemozoin nanocrystals. (a) SEM images of hemozoin nanocrystals n1–n5, labeled in Fig. 3. (b) Corresponding diamond-magnetic-microscopy images ($B_0 = 186$ mT) for each crystal. (c) Simulated magnetic images ($\chi = 3.4 \times 10^{-4}$, $B_0 = 186$ mT) obtained with nanocrystal dimensions inferred from (a). Only the crystal at the center of each SEM image is included in the model. (d) Line cuts of each nanocrystal (red, measured; gray, simulated), from which the field-pattern amplitude ΔB is inferred. A minimum feature width of ~ 400 -nm FWHM is observed for n5, close to the optical diffraction-limited resolution of our microscope. (e) $\Delta B(B_0) = 0$ (zero-coercivity assumption). (f) Histogram of ΔB ($B_0 = 350$ mT) of the 78 crystals exhibiting linear paramagnetic behavior (including n1–n4). The four crystals exhibiting superparamagnetic behavior (including n5) are excluded from the analysis. (g) Fitted slopes, $d\Delta B/dB_0$, as a function of crystal area, A , as determined from SEM images. The data are fitted with an empirical saturation function, $d\Delta B/dB_0 = S_{\text{max}}/(1 + A_{\text{sat}}/A)$, with $S_{\text{max}} = 16.5 \pm 1.4 \mu\text{T}/\text{T}$ and $A_{\text{sat}} = 0.17 \pm 0.03 \mu\text{m}^2$.

**FIG. 5.**

Synthetic hemozoin. (a) Confocal reflection image (excitation at 405 nm) of synthetic hemozoin nanocrystals on a diamond substrate. In total, 46 dark features are identified as likely hemozoin nanocrystals. (b) Corresponding diamond-magnetic-microscopy image at $B_0 = 350$ mT. 41 of 46 possible crystals exhibit an observable magnetic feature. (c) $B(B_0)$ curves for three synthetic hemozoin crystals labeled in (b). Solid lines are weighted linear fits. (d) Histograms of $d B/dB_0$ for natural and synthetic hemozoin crystals.

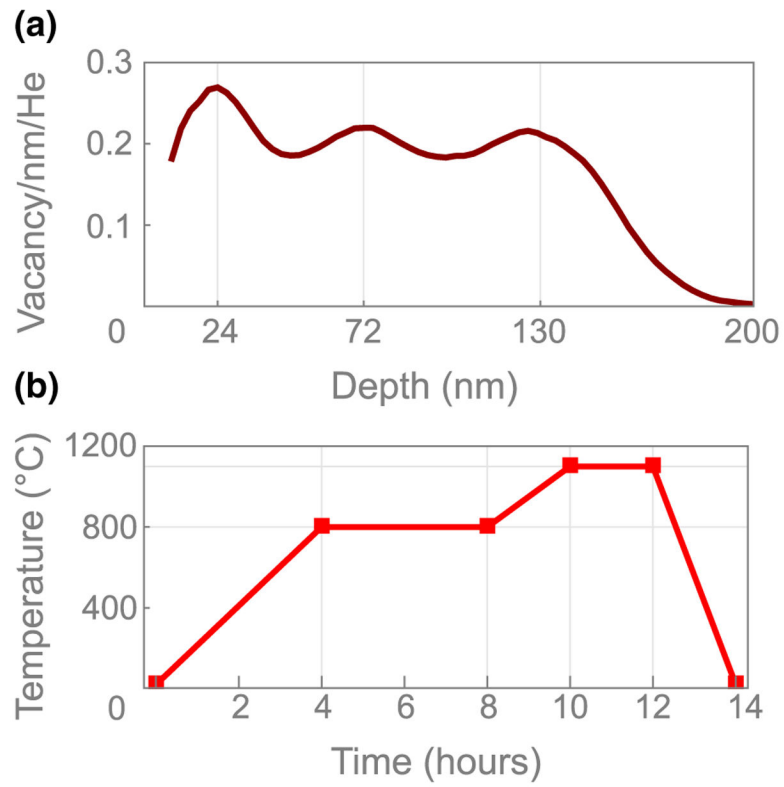

FIG. 6. NV-layer fabrication. (a) SRIM vacancy-depth profile for implantation conditions discussed in the text. (b) Time temperature graph for the annealing procedure used in this study.

FIG. 7. SEM processing. (a) Unprocessed SEM micrograph of the natural hemozoin sample. (b) A mask used to highlight and colorize hemozoin crystals and to attenuate their background. (c) Modified SEM image as shown in Fig. 3(b). (d) Unprocessed and (e) modified SEM images of hemozoin crystals n1–n5 addressed in Figs. 4(a)–4(e).

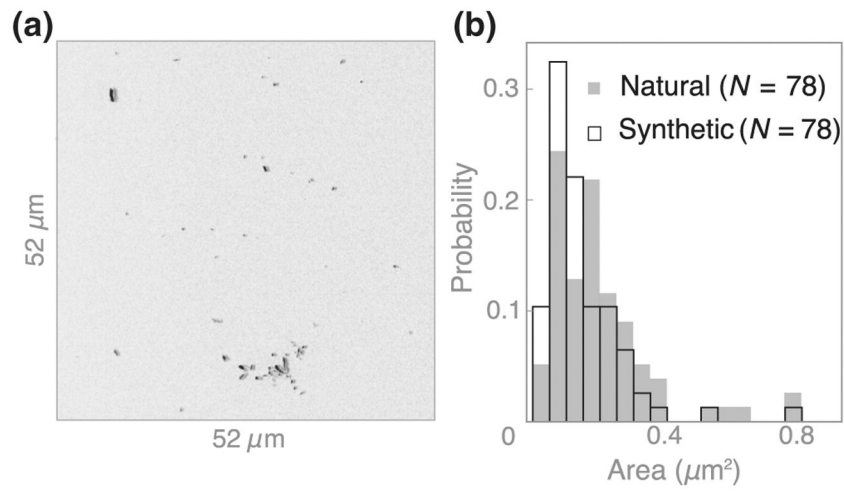

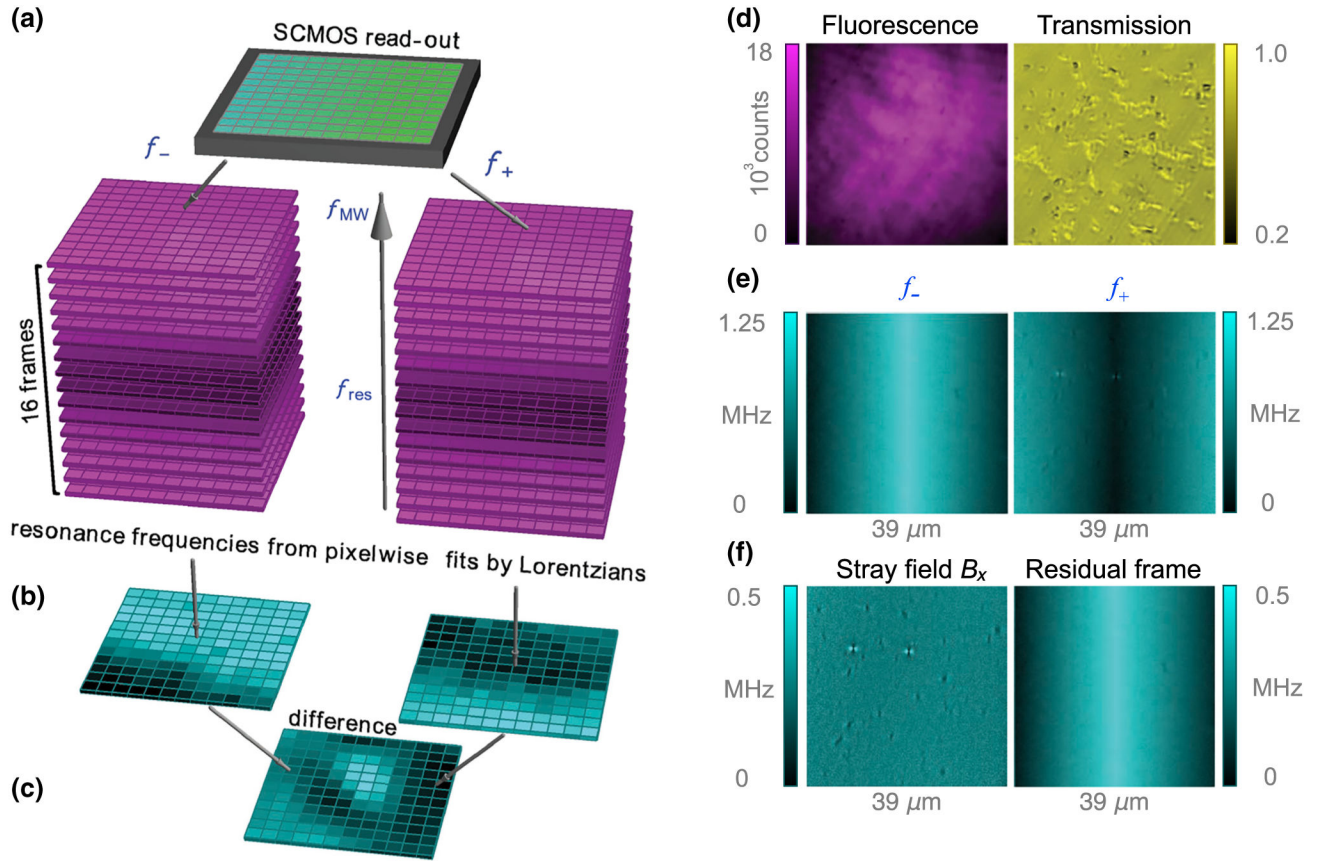

FIG. 8. Size comparison of natural and synthetic hemozoin crystals. (a) SEM image of synthetic hemozoin crystals dispersed on a diamond substrate. (b) Histogram of crystal area for natural and synthetic hemozoin crystals, as determined from SEM images in Figs. 7(a)–7(c) and 8(a).

**FIG. 9.**

Data processing. (a) Fluorescence images are acquired at each of 32 different microwave frequencies (16 frequencies for each of the f_{\pm} spin transitions). (b) For any given pixel, two 16-point ODMR curves (fluorescence intensity versus microwave frequency) are generated. Each ODMR curve is fit to a Lorentzian function to reveal the ODMR central frequencies for that pixel. This is repeated for each pixel, yielding two maps of ODMR central frequencies corresponding to f_+ and f_- . (c) The magnetic field pattern is obtained by subtraction of the images for f_+ and f_- , division by $2\gamma_{\text{NV}}$, and subtraction of the applied B_0 field. (d) An example fluorescence image for a fixed microwave frequency along with a bright-field transmission image of the same field of view. (e) Intermediate step showing separate maps for frequencies f_+ and f_- . (f) The final taken at $B_0 = 350$ mT, is proportional to stray magnetic fields, $\gamma_{\text{NV}}B_x = (f_+ - f_-)/2 - \gamma_{\text{NV}}B_0$. This is shown alongside a map of residual nonmagnetic shifts, $(f_+ - f_-)/2 - 2D$. Note that f_- is defined such that it is negative when $|-1\rangle$ is lower in energy than $|0\rangle$. The horizontally varying pattern is an artifact of the sCMOS camera's read-out dual-sensor. This artifact is present when rolling-shutter mode is used, but is eliminated by our subtraction procedure.

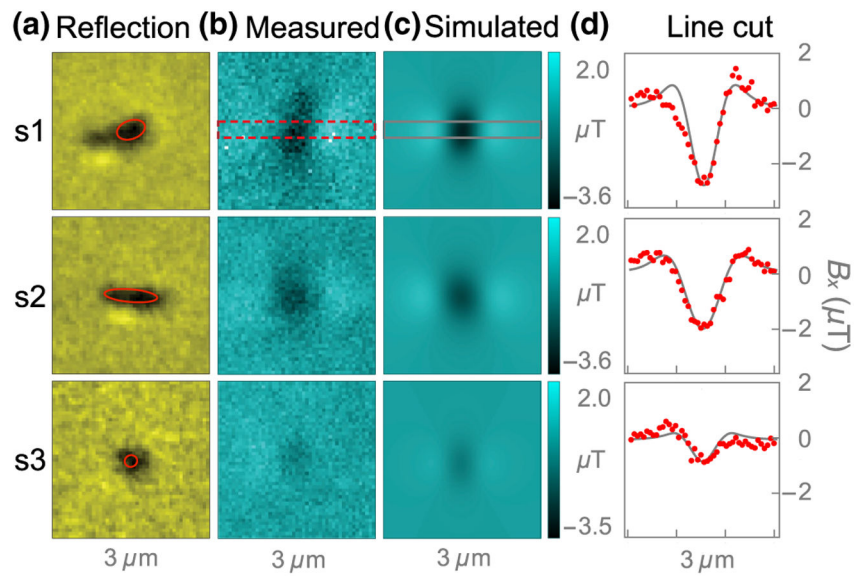

FIG. 10. Individual synthetic hemozoin crystals. (a) Confocal reflection images of hemozoin nanocrystals s1–s3, labeled in Figs. 5(a) and 5(b). The estimated area used for magnetostatic modeling is outlined in red. (b) Corresponding diamond-magnetic-microscopy images ($B_0 = 350$ mT) for each crystal. (c) Simulated magnetic images ($\chi = 3.4 \times 10^{-4}$, $B_0 = 350$ mT) obtained with nanocrystal dimensions roughly estimated from (a). (d) Line cuts of each nanocrystal (red, measured; gray, simulated), from which the field pattern amplitude B is inferred.

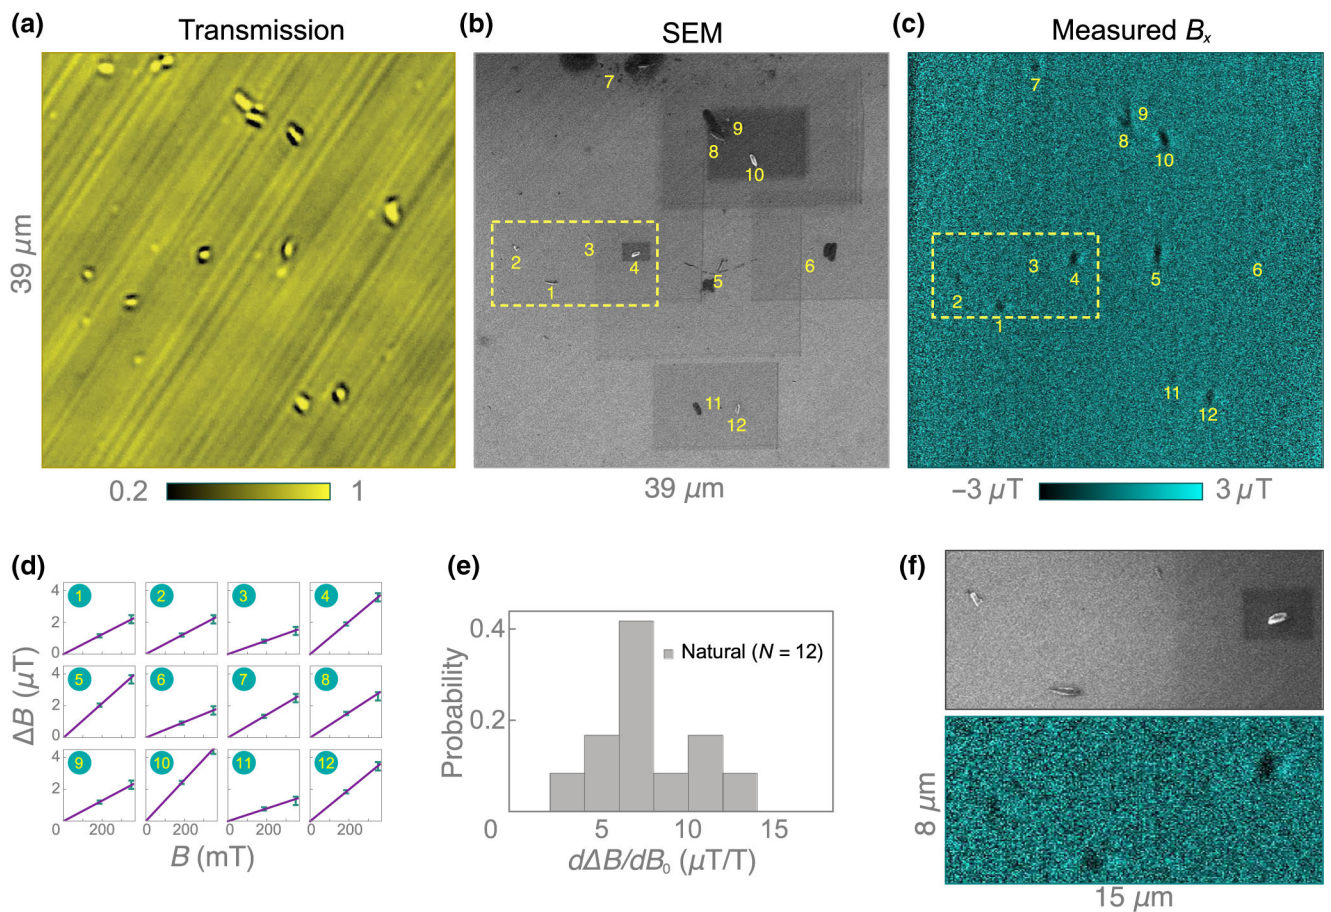

FIG. 11. Magnetic imaging of hemin crystals. (a) Bright field transmission image of hemin crystals. (b) Corresponding diamond-magnetic-microscopy image ($B_0 = 186$ mT). The inplane component of the applied field is labeled with an arrow. An out-of-plane component of similar magnitude is also present. Smaller particles are synthetic hemozoin crystals that are dispersed along with hemin crystals.

**FIG. 12.**

A second region of the natural hemozoin sample. (a) Bright-field transmission image of natural hemozoin crystals dispersed on a diamond substrate. (b) SEM image of the same nanocrystals. Dark rectangles are due to overcharging during zooming. (c) Corresponding diamond-magnetic-microscopy image at $B_0 = 350$ mT showing the positions of each nanocrystal. (d) $B(B_0)$ curves for all 12 hemozoin crystals. (e) Histogram of $d\Delta B/dB_0$ determined from the linear slopes in (d). (f) Magnified SEM and magnetic images of crystals 1–4.

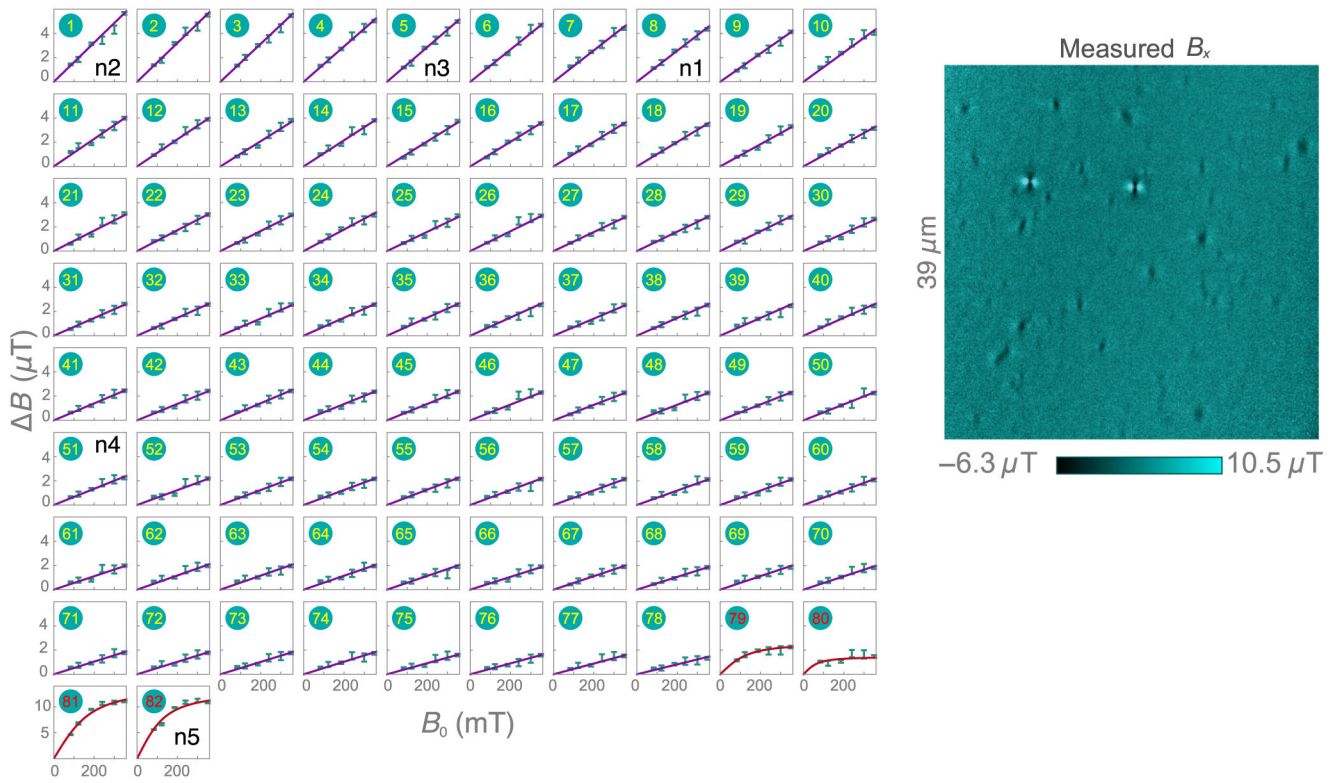

FIG. 13. Natural hemozoin: field-dependent magnetization. $B(B_0)$ curves for all 82 natural hemozoin crystals reported in Sec. IV (left). Magnetic image ($B_0 = 350$ mT) showing the positions of each nanocrystal (right).

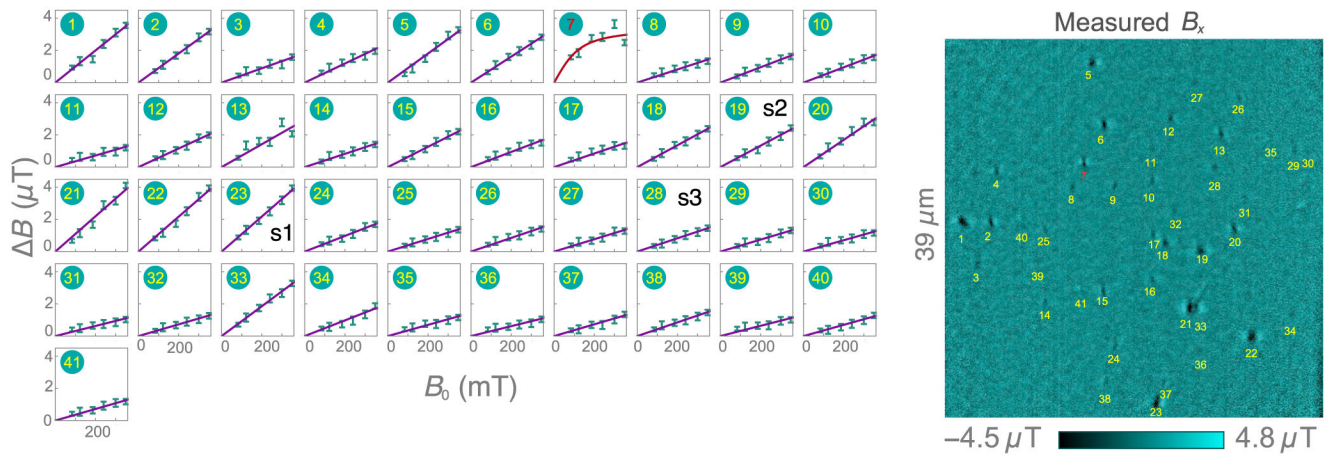

FIG. 14. Synthetic hemozoin: field-dependent magnetization. $B(B_0)$ curves for all 41 synthetic hemozoin crystals reported in Sec. IV (left). Magnetic image ($B_0 = 350$ mT) showing the positions of each nanocrystal (right).

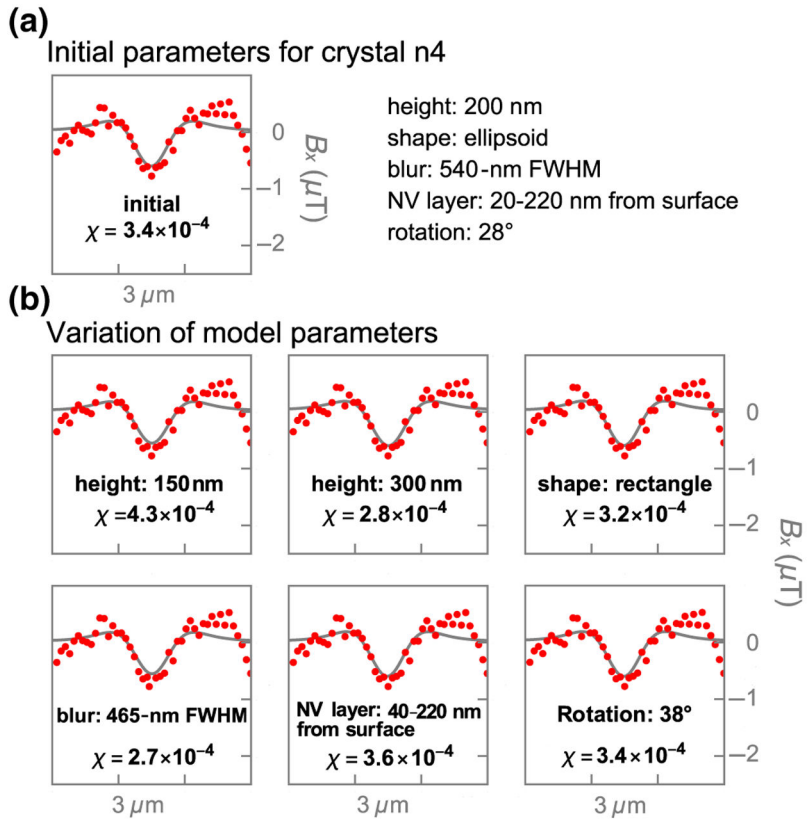

FIG. 15. Impact of model parameters on magnetic susceptibility χ . (a) Line cuts of measured (red) and simulated (gray) magnetic patterns from crystal n4 [reproduced from Fig. 4(d)] obtained with the initial model parameters shown on the right. (b) Simulated line cuts of n4 for different model parameters. Only one parameter is changed at a time. The varied model parameters and best-fit magnetic susceptibility values are shown as insets.

TABLE I.

Methods for label-free imaging of individual hemozoin crystals.

Imaging method	Physical observables	Penetration of probe	Frame rate (Hz)
Absorption microscopy [57]	Optical absorption	Optical field	~ 100
Polarization microscopy [58]	Birefringence or dichroism	Optical field	~ 100
Differential interference contrast [59]	Refractive index	Optical field	~ 50
Resonance Raman microscopy [60]	Vibrational structure	Intense optical field	~ 1
Third-harmonic generation [17]	Crystal structure	Intense optical field	~ 1
Diamond magnetic microscopy (this study)	Magnetic moment	dc or ac magnetic field	~ 1
