## ACKNOWLEDGMENTS

This thesis and my time as a master's student at UC Irvine was made possible through a variety of people that I would like to acknowledge and thank.

First, I would like to thank the professors, faculty, and staff at UCI's Institute of Transportation Studies for their time, knowledge, and dedication to providing a space for transportation research. In particular, I would like to thank my professor and advisor, Dr. Michael McNally, for his guidance on this thesis, as well as always having insightful and witty comments about everything in transportation and life. Your classes have cemented my interest in travel demand modeling and transportation, and I've always enjoyed our conversations about transportation and idiosyncrasies - each conversation always sets my curiosity bounding off in another direction.

In addition, I am also grateful to the other two members of my committee - Dr. Jin and Dr. Saphores, for their time and comments on this thesis and their time spent teaching and imparting general knowledge about transportation. I would also like to thank Dr. Houston, Dr. Marantz, and Sarah Catz in the urban planning department - your classes gave an understanding of how transportation is situated in the greater context of the urban environment.

I would also like to dedicate thanks to the friends I've made at ITS over the past two years, and some outside of UCI. In particular - to Monica Ramirez - thank you for always keeping me on track and rescuing me from troubles of my own creation, and for keeping me company in urban planning classes, I don't know how I could have done it without you. To Kat Lee, Lu Xu, Jiaqi Cheng, and Steven Ng - thank you for the laughs, the stress, and everything in between - I'm glad I've met you all and that you've become a consistent part of my life.

Last but not least - to my family - thank you to my parents, who have always supported me, even when it means moving more than five hours away from home and seeing you only three times a year. And to my brother, thank you too, for always lending an ear, sending over good textbooks, helping solve coding snafus, and providing free food.

# ABSTRACT OF THE THESIS 

# A Direct Demand Model of Commuter Rail in the San Francisco Bay Area 

 ByJennifer Kwong Master of Science in Civil Engineering University of California, Irvine, 2018<br>Professor Michael McNally, Chair

This thesis documents the development of a direct travel demand model for commuter rail in the San Francisco Bay Area. A direct demand model simultaneously estimates trip generation and attraction, which for this thesis would be trips between an origin-destination pair of stations. In the model, the number of trips assigned to an origindestination pair of stations is dependent on land use characteristics at the origin and destination stations in combination with travel time on the network during congested peak periods and via transit. The model uses a multiplicative direct demand model to estimate ordinary least square regression parameters for the origin-destination trips. From the model form, the resultant estimated regression parameters are elasticities, and as such, can be used to postulate the effects of the selected land use characteristics and network travel times upon the number of trips made.

At both the origin and destination, the location of the station within the central business districts of the San Francisco Bay region had the largest effect on trip generation and attraction. Higher employment density at the destination and a larger number of workers per household at the origin had a positive effect on trips, while the total number of
industrial workers at the destination and an increased number of two car households had a negative effect on trips. Longer travel times on transit appeared to have a positive effect on trips, yet longer travel times in congested peak periods appeared to have a negative effect on trips.

## INTRODUCTION

The continuing increase in population in urban areas has unsurprisingly led to a corresponding increase in driving, and thus congestion. This has led to a variety of ways to attempt to mitigate congestion - from adding additional transportation infrastructure to service the demand, to planning communities that encourage people to drive less, and to also reduce the amount of greenhouse gases emitted due to increased driving.

In recognition of the part that the transportation sector plays in anthropogenic climate change, the government of California passed two bills - Assembly Bill 32 (AB 32) and Senate Bill 375 (SB 375), targeted at reducing greenhouse gas emissions. As a result, the two bills have spurred an increased interest in understanding the relationship between travel behavior and land uses for governmental policy and industry, especially SB 375, which requires regional planning agencies (typically MPOs) to create a Sustainable Communities Strategy (SCS). ${ }^{1} \mathrm{AB} 32$ requires $1.2 \%$ of emission requirements to come from local governments, and one method in doing so is by changing development patterns to reduce emissions. ${ }^{2}$ SB 375 helps reinforce the goals established by AB32, and gives planning agencies more of a direct requirement in the ways they have to implement the GHG emission goals. The Sustainable Communities Strategy is meant to be a complement to the regional planning agencies' Regional Transportation Plan (RTP). The bill specifically states that "changes in land use and transportation policy, based upon established modeling methodology, will provide significant assistance to California's goals to implement the federal and state Clean Air Acts and to reduce its dependence on

[^0]petroleum." ${ }^{3}$ The most powerful method in which SB 375 encourages doing so is in its streamlining of development projects that fit with the SCS, even if they conflict with local plans, especially transit priority projects.

As evidenced by the importance accorded to transit in SB 375 - transit has often been touted as one of the methods that will help alleviate congestion. In addition to new transit projects, the concept of transit-oriented development, such as the changing development pattern policy suggested by AB32, has also been a popular suggestion to improve congestion. This paper aims to evaluate whether there are land use or socioeconomic characteristics, that contribute to differences in transit ridership at stations, in support of this idea. The paper develops a direct demand model for Caltrain, a linear commuter rail corridor in the San Francisco Bay Area, and integrates land use and travel time variables in a log-sum formulation in order to see if changes in land use density and other characteristics typically associated with transit-oriented development strongly influence transit ridership between stations.

Previous research has attempted to evaluate how land use has affected mode choice in an overall setting, with varying results. However, this model focuses specifically on ridership, as it would allow transit agencies to predict expected ridership growth at stations due to land development and adjust operation plans accordingly, or forecast more accurate ridership projections for new capital projects. In addition, it could allow planners to recognize baseline densities for land uses in zoning in order to encourage transit ridership, and supports modeling efforts for the goals that the California government has attempted to put into place with AB 32 and SB 375. It attempts to forecast both origin and

[^1]destinations, whereas most previous studies have chosen solely to focus on origin ridership. In addition, it uses an on-board travel survey and readily available GIS shapefiles to simplify the modeling data collection process, as the data and funds available to transit agencies is typically limited.

## Outline

Chapter 1 encompasses a literature review of topics relevant to land use and travel demand interactions, as well as transit ridership modeling. The thesis begins in Chapter 2 with an overview of the study area and travel survey data used for the model. In Chapter 3, the model is formulated and analyzed to see if there are correlations from the specified variables to transit ridership. Chapter 4 makes recommendations for enhancing the research done in this paper and for future efforts and concludes the thesis.

## Chapter 1: Literature Review

## Travel Demand Modeling

Travel demand modeling primarily began in the 1950s, with the United States' National Defense and Interstate Highway Act of 1956. The construction of the US interstate system was one of the first large-scale infrastructure construction processes in the modern era, and the four-step planning model that was researched, created and implemented during this time period to determine where these highways would go is still used today in transportation planning processes today. Planners of that time needed to understand travel behavior to predict future highway flows, and set a capacity for the highways they would construct. These early attempts to understand travel behavior focused on understanding how many trips would be generated from various land uses, and how they would travel from origin to destination. Requirements for transportation planning were first mandated by the Federal-Aid Highway Act of 1962, including that of models. ${ }^{4}$

As such, transportation models in the United States in practice have primarily focused on highways and car infrastructure, since that was what they were originally developed for. As other modes have increased in usage and popularity, the models have been modified to include techniques that can account for different modes, and to address the issues that arise in specifying increasingly complex models. Specific studies have been undertaken to inform transit ridership modeling, and many were synthesized and reviewed extensively in the 1996 Transit Cooperative Research Program Report, "Transit and Urban Form," and Taylor (2003).

[^2]
## Model Types

Travel demand modeling has primarily been done on a regional scale and using the traditional four-step model. The four step model as typically used in transportation planning is described in McNally (2007). The base activity system (land use characteristics) is used to determine how often trips occur (trip generation). Typical units of analysis are the transportation analysis zones (TAZs), which group together areas with similar characteristics. Trips are estimated in terms of the trips that a land use will produce, and how many it will attract. Then, in the following step (trip distribution), productions are distributed to attractions via calculated travel impedances (e.g. time or cost), reflecting person-trips. These person-trips are then split by mode, based on the understanding of mode-share for the region. Lastly, in route assignment, trips are assigned to segments of the network, and a time-of-day factor is also applied.

Activity based modeling has arisen as an alternate modeling approach to the fourstep model that integrates behavioral characteristics and economic utility choices of travelers and treats travel as a byproduct of the activity choices that an individual makes. Recker (1986), Bhat and Koppelman (1999) describe the fundamentals of activity-based modeling. Instead of obtaining trip-based data and outputting individual trips on links for a model, activity-based modeling seeks to replicate the set of choices that travelers make based on the pattern of activities that they typically do on a daily basis. Proponents of activity-based modeling argue for the importance of including the context of a person's daily behavior in determining what trips they will take. Activity based modeling allows for trip chaining and activity rescheduling, as they are options for travelers when faced with
travel choices, but trip-based modeling will incorrectly weight the effects of trip chains and cannot account for rescheduling.

The scale of these models is typically on a regional level, and as such, it is more difficult to examine the effects of mesoscopic neighborhood-scale changes for land use on transit line usage by using them to evaluate.

## Aggregate, Corridor, and Direct Demand Models

Direct demand models are a model formulation that in a single equation, simultaneously estimate trip generation, distribution, and mode split, and are similar to econometric models of demand. It is an aggregate model that can represent multiple travel choices in a single equation.

Ortuzar and Willumsen (2002) give a brief overview of direct demand modeling the models were first developed in the 1960s and fell out of favor in comparison to the standard travel models seen today. They also note that corridor and direct demand models are typically used in practice to substitute for full scale modeling, due to data limitations. A large amount of data is typically needed for conventional modeling, which typically is difficult to obtain in practice due to the inability ${ }^{5}$ to gather that amount of data on an as-needed basis. Corridor models typically remove assignment problems, which simplifies the network structure and creates savings in data collection and coding.

One of the initial formulations for direct demand models was the Kraft-SARC model, documented in Kraft (1963). The model form as formulated for estimating the demand in the Boston-Washington corridor is as follows:

[^3]$$
T_{i j m}=\beta_{m o} \prod_{r}^{R} A_{i j r}^{\beta_{m r}} \prod_{n}^{M} \prod_{s}^{S} C_{i j m s}^{\alpha_{m n s}}(m=1,2, \ldots M)
$$

In this formulation, $T_{i j m}$ is the travel demand between an origin i and destination j by mode $\mathrm{m}, A_{i j r}$ describes the socioeconomic activity variables between i and j , and $C_{i j n s}$ describes impedance variables (cost, travel time, etc) on mode m . R stands for the r-th variable within the set of socioeconomic activity variables, and sfor the s-th variable within the set of transportation impedance variables.

Talvitie (1973) was also one of the first to conceptualize a direct travel demand model for different modes, looking primarily at bus and rail modes to the downtown area. He based the estimated work trips on travel times and costs for each mode, and jobs in each zone, using ordinary least squares (OLS) and constrained least squares (CLS) to estimate the elasticities. Cost of travel appeared to be a minor factor, in comparison to access time to the downtown, supporting that travel demand is typically more responsive to travel time than pricing.

Direct demand modeling of the effects of service variation was done by Lago, Mayworm, and McEnroe. They examined elasticities of ridership response to service changes, and which areas were more responsive to service changes, finding that the response is similar acros modes, as are headway and vehicle-mile elasticities. However, they also found ridership is more responsive to changes in lower-service areas, as well as off-peak ridership.

De Cea et al. (1986) describe a formulation of a marginal demand model that simplifies the modeling approach for a particular problem by concentrating on the part of transport demand likely to be affected by the project or policy. They used this modeling
approach to examine an extension of the Santiago, Chile metro network, but note that it is a pragmatic methodology whose virtues and limitations can only be seen through practice.

Preston (1991) models rail demand in Britain with three different models, including a direct demand model which he calls an "aggregate simultaneous model." He attempted to forecast flow between stations based on population, residents in two social classes, and number of workplaces within 800 meters of rail stations, along with an index of competition variable that was defined as the travel time for rail divided by the sum of the travel time for rail, bus, and auto. Wardman (1997) also uses direct demand modeling to examine the interaction between modes in an inter-urban area in Britain. Using both the constant elasticity form and exponential form, and solely estimating rail demand, he develops a generalized time variable that combines station to station journey time, headways, and transfers, and subject to fare pricing, but removing the generation and attraction variables.

Cervero (2006) analyzes the effects of smart growth using direct demand models, as traditional models typically are not fine-grained enough to examine the effects of land use patterns and are meant to be applied over a regional area, not at a neighborhood level. He describes three direct demand modeling efforts for transit-oriented development scenarios, including Charlotte, the San Francisco Bay Area, and St. Louis, concluding that though direct demand modeling cannot supplant typical modeling procedures, they can supplement the models in developing order-of-magnitude effects of planning decisions.

## The "D's": Land Use Variables

Research has shifted towards how specific land use policies can affect travel forecasting. Cervero and Kockelman (1997) is one of the first articles to attempt to evaluate
how the primary dimensions (typically referred to in literature afterwards as the 3Ds) of density, diversity, and design influence travel demand. They noted that density, land-use diversity, and pedestrian-oriented design seem to affect travel behavior, though the influence is minimal.

Later articles explore how destination accessibility and distance to transit affect travel demand. Ewing and Cervero (2001) summarize how changes in the built environment can affect trip frequency, trip length, mode choice, vehicle miles traveled, and vehicle hours traveled, as well as review past literature. They assess how previous studies have defined different types of neighborhoods, and what those studies concluded about mode choice, trip frequency, or trip lengths. They note that dense, mixed-used development that is not connected to the greater regional network only provides minor improvements in travel times and lengths, which is why transit-oriented development has become more popular, as it combines local land use changes with high capacity transit, rather than relying on isolated land use changes in affecting mode choices.

## Additional Factors of Interest

Cao, Mokhtarian, and Handy (2009) evaluate the role that residential self-selection plays upon travel behavior, and in contrast to Mokhtarian's early research, concludes that with structural equation modeling, the built environment does have a strong influence on travel demand, more so than residential self-selection.

Others, mainly Donald Shoup, have evaluated how parking plays a role in travel demand. Shoup (1997) argues that unfairly priced parking (by making it free) has caused an excessive amount of driving, and Willson and Shoup (1990) notes that employer-paid parking subsidies greatly increases the occurrence of driving. After those subsidies are
removed, solo drivers tend to shift towards either carpooling or transit as commuting options. Another major discussion has also been the importance of regional variables rather than local accessibility in determining travel demand.

Handy (1992) notes the importance of evaluating how the existing structural form (regional accessibility) of the area ties into local accessibility measures in determining how much people will drive, based on the options that they have available. Further research by Spears, Boarnet and Handy (2010) for the California Air Resources Board evaluate how regional accessibility via transit, distance to the central business district, and number of destinations available nearby play a role in determining VMT.

## Mathematical Models and Variable Specification

Earlier models tend to use ordinary least squares regression, negative binomial regression, and other forms of linear regression models to estimate their travel behaviors. Vickerman (1972) is one of the first articles to explore how non-work travel is generated and attracted by various origins and destinations, and uses regression models to explore travel behavior in England. Washington, Karlaftis and Mannering (2010) describe in greater detail the process for regression estimation in transportation modeling. They outline assumptions that need to be fulfilled for regression modeling, and the differences between the commonly used regression methods. In particular, regression models require the data to consist of exogenous variables, which means that the variables have no observable influence on each other.

However, in social and behavior research, it is more likely the case that variables are endogenous and affect each other (e.g. population density will be related to transportation
network density, as noted in various papers.) ${ }^{6}$ As a result, more recent research has focused on structural equation modeling, which better captures the social and behavioral aspects of travel behavior and can account for endogenous variables, as well as machine learning to better replicate observed travel behavior from large data sets. Bagley and Mokhtarian (2002) use structural equation modeling to evaluate endogenous variables for residential neighborhoods in the San Francisco Bay Area affect travel demand. They conclude that land use configuration and travel patterns have no direct causal relationship, but are primarily due to correlations of those variables with each other, and the primary influencers of travel demand are travel attitudes, lifestyle, and sociodemographic variables.

Many of the studies in the 1996 TCRP addressed what factors have been observed to raise overall transit ridership in the specific total service areas of the analyzed transit systems, without attempting to make predictions on the station level. The primary conclusions of papers in the study noted that increasing jobs in the CBD tended to have a corresponding increase in ridership on transit systems, while moving jobs from the CBD to the suburbs tended to remove riders from the system, even if they had been previous transit users.

Cardozo, Palomares, and Gutierrez (2012) attempt to use geographically weighted regression and ordinary least squares to directly forecast transit ridership at the station level. However, they predict only ridership origins, and do not attempt to predict where riders will be attracted to based on travel costs. In addition, two out of the four selected variables that they used as predictors are the number of lines running to a station, as well

[^4]as suburban bus lines running to a station, which in reality, have strong feedback effects to ridership, even if the calculated multicollinearity is low.

## Travel Survey Data Review

A discussion of travel behavior analysis and transit demand forecasting should also reference the typical data used to inform the models, and also the limitations for analysis based on the data collection methods. Travel behavior data is typically taken from information sources provided by the government. On the federal level, the National Household Travel Survey (NHTS) is typically performed every eight years. The last dataset available for use is from 2009, and the 2017 survey is currently in the process of assembling the collected data for publication in 2018. ${ }^{7}$ Information included in the national survey includes household demographic data, vehicle data, trip purposes, mode choice, travel length (in distance and time), and regional transportation characteristics. It does not include travel information costs, route choices, changes in travel patterns over time, location-identifying characteristics, and rationale for mode choice. As a result, travel cannot be tied directly to individual traffic analysis zones (TAZs) or census block groups, which hinders land use and travel behavior interaction modeling efforts.

For research that requires data at that fine of a level, typically state departments of transportation or metropolitan planning organizations (MPOs) will conduct additional travel surveys every ten years. That data will typically include TAZ locations of the households that are surveyed, which allows for the households to be associated with specific census block groups and then land use characteristics. This allows for the specific

[^5]effects of land use variables and locations to be modeled against vehicle miles traveled or trip length, whereas the national survey primarily serves to model travel behavior against socioeconomic and demographic characteristics. These travel surveys are also typically for intra-regional trips and daily travel, but since 2001, long-distance trips have also been included as part of the NHTS' record.

The NHTS states that it is conducted via a random digit dialing, computer-assisted telephone interviewing survey conducted over an entire year, from the civilian population of the United States. The Southern California Association of Governments (SCAG) ${ }^{8}$ and other MPOs ${ }^{9,10,11}$ use similar methods to acquire data for their regional travel surveys. Stopher and Greaves (2007) reviews the limitations of the type of data that these surveys procure, as well as how they are conducted. The majority of travel behavior surveys are collected this way, but they note that most surveys underreport trips by approximately 20$30 \%$. The overall response rate for these surveys (when accounting for recruitment rate and completion rate) is also fairly low, at approximately $35 \%$, and non-respondents are households that tend to travel more or have more members. The first set of households tend to be underrecruited, due to their travel schedules, and the latter tend to not complete the surveys once recruited, since additional household members makes completing the surveys more arduous. Both of these limitations are significant, especially in terms of modeling VMT accurately. Those who travel significantly more often than the general population are a key group for modelers to be able to accurately represent. Underreporting

[^6]trips (especially if emissions models are being based off of VMT) will correspond to emission rates that are higher in actuality than those that the model predicts. Though later models, once accounting for historical trends, will likely be able to capture this irregularity, this will only occur after the additional particulate matter has been emitted and damage has already been incurred, and only if the models are validated against previous data and models. Do-not-call registries and screening for telemarketers has also reduced the number of households willing to be recruited for the surveys, and likewise, the survey data's quality has decreased as the sampling has become less accurate.

There are specific limitations in using household travel survey data to estimate transit behavior, and transit demand analysis is typically done by supplanting typical household travel survey data with on-board travel surveys. Typical household travel surveys tend to undersample transit riders. For example, only $3 \%$ of the trips observed in the California Household Travel Survey (CHTS) are made by transit, which covers both bus, commuter rail, light rail, and metro rail systems across California over multiple metropolitan areas, whereas statewide in a similar year (2013) ${ }^{12}$, the state saw roughly 5.3\% of work trips made by transit. ${ }^{13}$ This data is split over multiple transit systems and multiple geographic areas, which may behave differently due to system design and overall transit coverage in the urban area, making it hard to evaluate variations in user behavior for a single system.

The proliferation of smartphones has also added another method for which travel behavior can be recorded and measured. Haghani (2010) describes how bluetooth sensors

[^7]use the Machine Access Control (MAC) addresses of smart phones, cameras, and other connected devices passing through the sensors' area to determine accurate travel times on roads. Travel time data via smartphones is also recorded and used commercially by corporations such as Microsoft and Google in order to estimate real-time traffic for their proprietary mapping software. Ridesharing companies also have a treasure trove of travel data in their databases, and have begun partnering in limited capacity with governments to analyze and use said data. ${ }^{14}$

Smartphone data has also been used to record travel path and routing choice data that previously was difficult to acquire. Hood, Sall and Charlton (2013) use smartphones to acquire bicycle route choice data in San Francisco, and then pair that data with a network model to better understand which routes bicyclists prefer. They analyze road segment variables such as the presence of bicycle lanes, length, turns, grade of the segment, traffic volume, speeds, number of lanes, crime rates, and time of day. Nitsche (2012) and (2014) also describes how smartphones can be used to supplement and recreate the data in traditional travel surveys, and the relative accuracy of the models based on different types of modes, e.g. walking, biking, train, and automobile. Gong, Chen, Bialostozky, and Lawson (2011) designed a GIS algorithm to process data from GPS units to determine mode and route choice and other travel behaviors in New York City using the city's multi-modal transportation network and validate their data against the self-reported travel diaries for fairly high accuracy in reporting (at approximately 80\%). Cottrill et. al (2013) discuss how a smartphone-based travel survey can be developed, with a test case in Singapore for the Land Transport Authority (the city-state's urban planning agency.)

[^8]It is worth noting that smartphone data may tend to over represent certain economic classes, based on how data is collected. The initial cost of purchasing a smart phone may be a factor, as well as how recruitment efforts for these surveys are targeted. The Hood (2013) survey contacted local bicycle coalitions and university groups and asked them to send out a link for downloading their survey application, which gave out incentives for response - but the recruited are more likely to be highly educated and with greater purchasing power. However, smartphone ownership covers a huge swath of the American population nowadays - the Pew Research Center estimates that 77\% of all Americans now own smartphones, as well as 64\% of individuals in lower-income households earning less than $\$ 30,000$. Thus, the possible skewing of data based on smartphone owner demographics may be less of a factor than what they were previously. ${ }^{15}$

## Current Relevance

Climate change issues have come to be one of the driving motivators in transportation research, especially with the awareness that the transportation sector is responsible for $27 \%$ of the greenhouse gas (GHG) emissions within the United States. ${ }^{16}$ Vehicle miles traveled (VMT) per capita has a high correlation with declines in local environmental quality (via particulate matter and road runoff) and increases in energy resource consumption. As more miles are driven, more particulate matter is emitted, more acreage is set aside for transportation infrastructure, and more fossil fuels are consumed. Cervero and Murakami (2010) note that GHG emissions can be roughly determined by multiplying miles per gallon (fuel consumption) versus the fuel's carbon content, and then

[^9]by a person's vehicle miles traveled. The first are determined by the technology advances available for transportation, and the latter by the activities that the person chooses to partake in as well as their origin (which is typically their residence.) They refer to these two concepts as sustainability mobility - for advances in transportation technology, and sustainable urbanism - for improved land-use planning measures that reduce total vehicle miles traveled. They also note that the majority of research has focused on the sustainable mobility portion, as the benefits in improving transportation technology are more easily measurable. At present, the available literature tying changes in land use to VMT and GHG reductions has been inconsistent in determining the benefits that can be attributed to differing land uses, though a number have concluded that there are measurable, if small, benefits to doing so.

## Chapter 2: Study Area and Background

## Study Area Overview

The study focuses on the Caltrain commuter rail network, which is a commuter rail line with only one line and 32 stations that serves the cities and counties in between the two cities of San Francisco and San Jose (Figure 1.) It averages approximately 62,000 riders on the weekdays, and 12,000 on the weekends. Two highways, US-101 and I-280, parallel the Caltrain system for its length, and are marked on the figure below. In the year the study data was acquired, Caltrain was notable for being one of the few American transit systems that saw ridership gains rather than declines, due to the strong economic growth of the Bay Area. Ridership gains have also been driven by increased congestion on the two highways paralleling the lines (US-101 and I-280) for the majority of the peak periods during the same time period.

Figure 1: Caltrain Stations and Service Area

## Data Overview

The data used for this study came from five primary sources - the EPA's Smart Location Database, the 2014 Caltrain On-Board Travel Survey, Google Maps, and Caltrans' GIS and Performance Measurement System (PeMS) Databases.

Land use data was obtained through the EPA's Smart Location Database. The EPA first published the SLD in 2012, with a complete update in 2014. It is intended to be a nationwide geographic data resource for measuring location efficiency and is available for public use in a GIS format. Sample variables included within the dataset include (on a block group level) - residential density, population density, employment density, employment and housing entropy, street intersections per square mile, distance to nearest transit stop, destination accessibility via car and transit, and more. Land use and accessibility measures were computed for the SLD based on typical measures used previously in transportation research. The data year for the SLD data matches that of the MTC Caltrain data, so it does not need to be scaled for population/job changes. Google Maps and PeMS were used to obtain free flow and congested travel times. GIS data obtained from the Caltrans system included the Caltrain rail network, highway network in the Bay Area, and stations on the network. The Caltrain webpage also provided the total number of parking spaces at each Caltrain station.

MTC's Caltrain On-Board Travel Survey data included information about traveler socioeconomic data, such as workers in household, vehicles in household, household income; trip data, including location (boarding and alighting stations, trip departure hour and predicted return hour), as well as information about the home TAZ, destination TAZ, school TAZ, and workplace TAZ. In addition, a GIS shapefile of the TAZs was provided. The
survey consisted of two major portions - the on-to-off element, in order to identify boarding and alighting patterns of transit riders, and to expand the results of the main survey. The main survey was meant to create a detailed profile of typical riders on Caltrain, and gathered socioeconomic data. Over 19,000 on-to-off surveys were completed, as well as approximately 5,000 main surveys. ${ }^{17}$ A table of the origin and destination trips by station pairs follows.

## Chapter 3: Model Methodology, Formulation, and Results

## Methodology

In order to calculate the land use variables, the service area of the station had to be defined. A distance threshold for the catchment area of the stations was defined by taking a Euclidean distance of 0.5 miles around the station, which is the typical walking distance used for rail station service areas in most research, and has been extensively studied (Parsons Brinckerhoff 1996, Walters and Cervero 2003, O’Neill Ramsey and Chou 1992). The data from the census block groups that had portions which fell within the 0.5 mile buffer were aggregated. The counts for variables that were hypothesized to correlate with ridership were created for each station, and then divided by the unprotected acreage to create density measures for the station catchment areas. Counts and unprotected acreage for each census block group was taken from the EPA's Smart Location Database, which in turn obtained its data from the US Census's TIGER shapefiles. Land use variables that were created in this step are listed below (Table 2), and were taken from the variables of interest previously reviewed and established in the literature review. A table of values by station for the selected variables of interest (Table 3) follows the hypothesized variables.

Table 2: Hypothesized Ridership Variables

| Variable | Description |
| :--- | :--- |
| Population | Population of census block groups that have at least some <br> portion falling within the 0.5 mile station catchment area, <br> abbreviated as 0.5 mile station catchment area CBGs <br> hereafter |
| Population Density | Calculated population divided by the sum of unprotected <br> acreage of in the 0.5 mile station catchment area CBGs |
| Housing Units | Housing units in the as 0.5 mile station catchment area CBGs |
| Housing Density | Calculated housing units divided by the sum of unprotected <br> acreage of in the 0.5 mile station catchment area CBGs |
| Workers | Total workers in station catchment area |
| No-car households | Non-car households in the 0.5 mile station catchment area <br> CBGs |
| One-car households | One-car households in the 0.5 mile station catchment area <br> CBGs |
| Two-car households | Two-car households in the 0.5 mile station catchment area <br> CBGs |
| Employment | Total jobs in the as 0.5 mile station catchment area CBGs |
| Office Employment | Total office jobs in the as 0.5 mile station catchment area <br> CBGs |
| Industrial Employment | Total industrial jobs in the as 0.5 mile station catchment <br> area CBGs |
| Entertainment <br> Employment | Total entertainment jobs in the as 0.5 mile station <br> catchment area CBGs |
| Retail Employment | Total retail jobs in the as 0.5 mile station catchment area <br> CBGs |
| Employment Density | Calculated total jobs divided by the sum of unprotected <br> acreage of in the 0.5 mile station catchment area CBGs |
| Parking spaces | Parking spaces at the station |
| Land-use mix | Entropy mix calculated via employment and household <br> entropy |
| Network density | Road network density for the 0.5 mile station catchment <br> area CBGs |
| Generated-variable that flagged the two central business <br> districts (San Jose and San Francisco) |  |

Travel costs were calculated using congested travel time on highways against travel time on the Caltrain network. Free flow travel time was estimated using the average time at 3 am from station to station using Google Maps. Then, peak period travel time on the highway was estimated using the average travel time index from PeMS during peak periods for the stretch of highway corresponding to the Caltrain link. The free flow travel speed was multiplied by the travel time index to get a time estimate, as the travel time index is defined by PeMS as the ratio of the average travel time for all travelers in a certain area to the free-flow travel time. The PeMS data used was taken from two weeks in October 2014 (during the same time period as the on-board travel survey) for Tuesday, Wednesday, and Thursday each week and averaged to best replicate typical conditions. Travel time on the Caltrain network was calculated using the published Caltrain timetables.

The provided Caltrain data was synthesized to create origin and destination pairs from the survey data (Table 4.) The weighting factor attributed to each trip was summed based on the home station and destination station provided by the survey respondent. The accuracy of the home and destination station for the respondents was checked by matching the stations to the provided home TAZ code and destination TAZ code. The home TAZ was considered the origin TAZ, and the employment/school/other TAZ would be considered the destination TAZ. In addition, a table of origin/destination pairs by station was also created and follows below.

## Formulation

The aggregate ridership model as tested consisted of two formulations. One replicated typical methods of estimating ridership via ordinary least squares regression, in order to validate hypothesis about variables' effects on ridership.

The first was formulated as
$T_{i}=f\left(\right.$ origin land use charecteristics) and $T_{j}=$ $f$ (destination land use charecteristics) Where

$$
\begin{aligned}
& T_{i}=\text { number of trips originating at station } i \\
& T_{j}=\text { number of trips originating at station } j
\end{aligned}
$$

The second tested a log-sum formulation that related the land use characteristics at each end to the number of riders on its origin/destination station pair, and included traveltime costs between stations for both transit and congested peak speeds. A hypothesized relationship for ridership between stations, travel time between stations, and land use variables at origin and destinations was proposed in the form of:

## $T_{i j}$

$=f($ travel time, origin land use characteristics, destination land use characteristics)
This posits that the interaction between two locations (via trips between the two locations) is related to characteristics of urban development at the origin and destination, as well as taking into account the travel time between destination and origin. The formulation was tested as:

$$
T_{i j}=T_{i} * T_{j} * t_{i j}
$$

Where:

$$
\begin{aligned}
& T_{i j}=\text { trips between station } i \text { to station } j \\
& T_{i}=\text { trips originating at station } i \\
& T_{j}=\text { trips destined to station } j
\end{aligned}
$$

$$
t_{i j}=\text { travel time between } i \text { and } j
$$

As the model seeks to estimate the effects of the independent variables upon the dependent variables, a log-log transformation of the variables was taken in order to produce an equation that could estimate the percent change in the dependent variable (trips between a station pair) with a percent change in the independent variables. The result could then be transformed back to determine the predicted number of trips for that station pair. This leads to a form:

$$
\log \left(T_{i j}\right)=\log \left(T_{o}\right)+\log \left(T_{j}\right)+\log \left(t_{i j}\right)
$$

Direct forecasting of ridership at a station level has been done primarily with ordinary least squares regression or multiple regression analysis, which is seen in Parsons Brinckerhoff 1996, Cardozo et. al 2012, Cervero 2006. In addition, this replicates the estimation methods of the four-step model (McNally 2007), which tends to use regressions to estimate trips. This method was used to estimate origins and destinations from the available land-use variables. The model would ideally be able to predict the variation in ridership from land-use, before using the variables in the log-sum formulation.

## Model Estimation, OLS

The final model for origins incorporated three independent variables, which were households owning 2-cars or more, total workers in the catchment area, and the central business district variable. These three variables were all statistically significant at the 0.05 level, and explained approximately $68 \%$ of the variation found within the destination data. None of the variables appeared to show multicollinearity, based on their variance inflation factors (VIF). The variables also appeared to be correlated with the data in the hypothesized ways - an increase of households owning two or more cars in the station
catchment area saw a decrease in transit trip origins, and increasing the number of workers in the catchment area also seems to correlate with increased transit trip origins. The two stations in the CBDs of San Jose and San Francisco also were associated with an increased number of origins.

Table 5: Final OLS Model, Origins

| Variable | Coefficient Estimate | Standard <br> Error | $t$-Statistic | Probability | VIF |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Intercept | 1432.9774 | 603.9327 | 2.373 | 0.0257 | - |
| Households with two or more cars | -1.6215 | 0.7019 | -2.310 | 0.0294 | 6.54 |
| Total workers | 0.8043 | 0.3550 | 2.266 | 0.0324 | 7.24 |
| CBD | 6499.4585 | 1066.3058 | 6.095 | . 00000227 | 1.36 |
| \# of observations | 29 |  |  |  |  |
| \# of variables | 3 |  |  |  |  |
| Adjusted $R^{2}$ | 0.6893 |  |  |  |  |
| $R^{2}$ | 0.7225 |  |  |  |  |
| Residual standard error | 1246 |  |  |  |  |
| Degrees of freedom | 25 |  |  |  |  |
| $F$-statistic | 21.7 |  | $p$-value (F-statistic) | . 0000003881 |  |

In addition to the final model, other models for origins were tested, which included the two variables for single-car households and no car household with the other tested variables, as well as including population and parking spaces at the station. However, the correlations given by the coefficients and their significance levels were less significant, and also had problems with redundancy as indicated by their variance inflation factors. The model coefficients for the variables of interests are presented below.

Table 6: Preliminary OLS Model, Origins - Single Car, Zero Car Households

| Variable | Coefficient Estimate | Standard Error | $t$-Statistic | Probability | VIF |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Intercept | 1138.0675 | 706.9632 | 1.610 | 0.12108 | - |
| Zero-car households | -0.1372 | 1.7877 | -0.077 | 0.93949 | 8.57 |
| One-car households | 1.240 | 0.5516 | 2.038 | 0.05322 | 9.64 |
| Households with two or more cars | -0.9679 | 0.7808 | -1.240 | 0.22763 | 10.47 |
| Total workers | 0.1421 | 0.3871 | 0.367 | 0.71696 | 11.13 |
| CBD | 4311.9165 | 1408.1324 | 3.062 | 0.00552 | 3.07 |
| \# of observations | 29 |  |  |  |  |
| \# of variables | 3 |  |  |  |  |
| Adjusted R ${ }^{2}$ | 0.7596 |  |  |  |  |
| $R^{2}$ | 0.8025 |  |  |  |  |
| Residual standard error | 1096 |  |  |  |  |
| Degrees of freedom | 23 |  |  |  |  |
| F-statistic | 18.7 |  | $p$-value (F-statistic) | . 0000002005 |  |

A model consisting of the zero-car and one-car households, with CBD, and population, and parking spaces at stations variables was also tested, but likewise, had problems with redundancy, even if it explained additional variation in the model and the correlation coefficients passed typical levels of significance.

Table 7: Preliminary OLS Model, Origins - Additional Variables

The final model for destinations incorporated three independent variables, one of which was the central business district indicator variable, and the other two related to employment - specifically, employment density and total industrial employment. These three variables were all statistically significant at the 0.001 level, and explained approximately $75 \%$ of the variation found within the destination data. None of the variables appeared to show multicollinearity, based on their variance inflation factors. The variables also followed the expected correlation - stations with a greater employment density in the catchment area were likely to have more trip ends. The two stations located in the two central business districts that anchored the census statistical area also had more
trip ends. A higher number of industrial workers seemed to be associated with less trip ends.

Total employment was also tested instead of employment density, and also saw a statistically significant correlation at a probability of 0.06 and a t-value of 1.940 . However, the total employment model had a greater standard error of 2743 , lower adjusted $\mathrm{R}^{2}$ and $\mathrm{R}^{2}$ values ( $0.5624,0.5099$ ), and a lower F-statistic, and so the employment density model was chosen for inclusion instead.

Table 8: Final OLS Model, Destinations

As the census business district stations appear in both formulations as a significant factor, It could be hypothesized that stations in these areas tend to behave significantly differently than other stations - they both produce and attract a significant amount of trips, irrespective of other land-use factors. However, this is also because central business
districts tend to be some of the densest, concentrated employment centers of their geographic region, and San Francisco and San Jose also hold a significant amount of residents for the region. A table (Table 9) of the selected variables and their values for each station follows on the next page.
Table 9: Station Land Use Variable Values

| STATION | ORIGIN | DESTINATION | CBD | 2 Car + Ownership Households | Total Industrial Workers | Total Workers | Employment Density |

## Model Estimation, Log-sum

The direct demand model is estimated using the form In the previous sections, an assessment of the land use variables hypothesized to have an effect on creation of trips originating and trips destined to stations was established. The equations for those are as follows:

$$
\begin{aligned}
& T_{o}=1432-1.625 H_{2} H_{2 \text { car }}+0.8043 W_{\text {total }}+6499 C B D \\
& T_{j}=-1147+3529 E_{\text {density }}-0.1918 W_{\text {industrial }}+6164 C B D
\end{aligned}
$$

Where:

$$
\begin{aligned}
& H H_{1 c a r}=\text { households owning } 2 \text { or more cars } \\
& W_{\text {total }}=\text { total workers } \\
& E_{\text {density }}=\text { employment density } \\
& W_{\text {industrial }}=\text { total industrial workers } \\
& C B D=\text { identifier for central business district location }
\end{aligned}
$$

Congested network travel times and travel times between stations via transit were also obtained in order to see if there was a relation between an increase in network travel time and transit time to ridership.

The general multiplicative form of a direct demand model can be formulated as:

$$
T_{i j}=a^{X^{b}} Y^{c} Z^{d}
$$

Where $\mathrm{a}, \mathrm{y}$, and z are some hypothetical parameters (in this case, land use and travel time.)
As $e^{T_{i j}}=\left(\frac{d T}{d X}\right)\left(\frac{X}{T}\right)=b$, the equation can also be written as a log-log formulation of:

$$
\log \left(T_{i j}\right)=\log (a)+b \log (X)+c \log (Y)+d \log (Z)
$$

Using the $\log \log$ formulation, the following model was developed:
Table 10: Final Direct Demand Model Estimation

The model then becomes:

$$
\begin{aligned}
\log \left(T_{i j}\right)= & 2.263 \log \left(C B D_{j}\right)+0.819 \log \left(E_{\text {density }_{j}}\right)-0.1628 \log \left(E_{\text {industrial }_{j}}\right) \\
& \quad 0.9911 \log \left(H H_{2 \text { car }_{i}}\right)+1.821 \log \left(C B D_{i}\right)+1.311 \log \left(H H_{\text {workers }_{i}}\right) \\
& -3.98 \log \left(T T_{\text {am }}\right)+3.6452 \log \left(T T_{\text {transit }}\right)
\end{aligned}
$$

In terms of the land use variables, the relative magnitude and direction of the land use variables effect in the log-log formulation on trips produced at origin and attracted to destination stays similar to that observed in the linear formulations. The station being located either in a CBD for its origin or destination appears to be one of the biggest factors in whether a transit trip will occur at it. Congested travel times between stations and
transit travel times between stations were considered to see if there was an effect upon ridership. A table of the predicted values of the trips by origin and destination follows below in Table 11.

The model appears to account for approximately $40 \%$ of the variation in trips between OD pairs, and a comparison follows below. The model appears to underpredict trips between station pairs that have higher ridership, and a comparison of the estimated origins and estimated destinations against the observed origins and destinations follows in Table 12. This is less apparent in the log-log formulation, as seen in the tabularized summary statistics for the model and the graph below.

Figure 2: Log of Trips vs Log of Predicted Trips for OD Station Pairs
However, when examining the log-log residuals, it is more apparent that the model has difficulty making an accurate prediction for the station pairs with higher ridership, and that a pattern exists for the residual.

Figure 3: Residual Plot of the log of Trips vs. Predicted Trips

Thus, improvements on the model form could likely be made in order to account for the variation in ridership a higher OD-pair stations.

## Chapter 4: Conclusion, Future Work and Recommendations

In conclusion, the model sought to evaluate the creation of a direct demand model for transit ridership that would be able to integrate origin and destination land use characteristics, in addition to network travel time information. The model used a multiplicative direct demand model to estimate elasticities between land use variables and network characteristics for the origin-destination trips.

At both the origin and destination, the location of the station within the central business districts of the San Francisco Bay region had the largest effect on trip generation and attraction. Higher employment density at the destination and a larger number of workers per household at the origin had a positive effect on trips, while the total number of industrial workers at the destination and an increased number of two car households had a negative effect on trips. Longer travel times on transit appeared to have a positive effect on trips, yet longer travel times in congested peak periods appeared to have a negative effect on trips.

Future work would include the examination of additional variables to see if any explanatory variables could account for the variation at stations that generate and attract more riders. High ridership stations are usually the points of interests for agencies, in order to evaluate peak load and peak load capacities. As such, a model that could accurately evaluate the effects of changing land use characteristics and travel times as a result of land development in a transit corridor for high ridership station would be beneficial. A likely explanatory variable could be subcenters for employment. Adding subcenters as a variable would require a regional analysis for subcenters to be determined. In addition, future work could examine the effects of aggregation at a TAZ level instead of a station level, which
would likely be useful for evaluating land development projects. Future work could also evaluate if this model form works on a non-linear corridor system with multiple branch lines, which would likely add to the complexity.

More models similar to this could also be easily constructed if more transit agencies had readily available data, either from obtaining the data from transit card usage or performing similar on-board travel surveys.
